The umbilical cord venous and arterial blood lactate concentrations were higher than the maternal venous blood lactate concentrations in all three groups. The glucose infusion in group 1 caused a greater increase in the blood lactate concentration in the umbilical cord vein ($p < 0.001$) and artery ($p < 0.002$) when compared with that of groups 2 and 3. In addition, the blood lactate concentration was higher in the umbilical artery than in the vein in all three groups. The blood lactate concentration in the neonates at 30 minutes after birth was significantly higher in group 1 than in groups 2 and 3 ($p < 0.004$), but by 90 minutes the lactate concentration in the three groups of neonates was not statistically different.

Plasma insulin. The initial maternal plasma insulin concentrations in groups 1, 2, and 3 were 8.3 ±

Table II. Acid-base status at delivery

Values are mean ± SD.
*$p < 0.05$ (group 1 compared with groups 2 and 3).

6.2, 10.5 ± 5.5, and 12.6 ± 9.0 μU/ml, respectively (Fig. 3). The glucose infusion in group 1 caused a short-term rise in the insulin concentration so that at 20 minutes the plasma insulin concentration was 80.7 ± 44.8 μU/ml ($p < 0.0001$). At delivery, the maternal plasma insulin concentration in group 1 remained significantly elevated at 58.9 ± 38.4 μU/ml ($p < 0.002$) with the plasma insulin concentrations in groups 2 and 3 remaining unchanged. The insulin concentration in the umbilical cord vein (65.9 ± 67.9 μU/ml) and artery (55.6 ± 66.5 μU/ml) at delivery in group 1 was also significantly elevated when compared with the other two groups ($p < 0.02$). The insulin concentrations could not be measured in all the neonates at 30, 60, 90, and 120 minutes because of limited blood sample size. However, the neonatal insulin concentrations in groups 2 and 3 remained <3.5 μU/ml while in the neonates of group 1 higher insulin concentrations were maintained at 30 and 90 minutes after birth.

Acid-base status. The maternal venous pH before the infusion was similar in the three groups. By the end of the infusion, the maternal pH in group 1 (7.36 ± 0.03) was significantly lower than the pH in group 2 (7.38 ± 0.2) and group 3 (7.39 ± 0.02) ($p < 0.05$). As shown in Table II, the maternal pH at delivery was similar between the groups. However, the umbilical arterial pH in group 1 (7.21 ± 0.06) was significantly lower than the umbilical arterial pH in group 2 (7.27 ± 0.12) and group 3 (7.27 ± 0.06) ($p < 0.05$). The umbilical venous blood pH in group 1 (7.31 ± 0.04) was also significantly lower than the umbilical cord vein pH in group 2 (7.35 ± 0.07) and group 3 (7.34 ± 0.04) ($p < 0.05$). In the neonatal period, there was a tendency for lower venous pH values in the neonates from group 1. However, no conclusions can be made as complete studies were done in only eight neonates.

Additional acid-base results in the maternal vein at delivery and the umbilical cord vein and artery of the three groups are shown in Table II. There was a significantly higher umbilical cord artery P_{CO_2} in the glucose-infused group. The umbilical arterial hemoglobin oxygen saturation in the glucose group (11.8 ± 7.0) was significantly lower than that of the Ringer's lactate (22.7 ± 12.3) or normal saline solution (17.6 ± 6.7) groups ($p < 0.05$).

β-Hydroxybutyrate and triglycerides. As shown in Table III, acute glucose infusion in group 1 was associated with a significant decrease in the concentration of β-hydroxybutyrate in the maternal blood at delivery ($p < 0.001$). In addition, the umbilical venous ($p < 0.003$) and arterial ($p < 0.04$) concentrations of β-hydroxybutyrate were lower in group 1 than in groups 2 and 3. The concentration of β-hydroxybutyrate in the maternal plasma tended to rise in the Ringer's lactate and normal saline solution groups. The triglyceride levels in the three groups demonstrated wide variations with large standard deviations within each group. No significant differences in the mean triglyceride levels between the groups were identified.

Serum electrolytes, carbon dioxide, and blood urea nitrogen. The serum electrolytes, carbon dioxide, and blood urea nitrogen were similar in the three groups. Acute glucose infusion significantly decreased the serum sodium level from 137 ± 3 to 131 ± 3 mEq/L ($p < 0.01$). No significant change in other electrolytes, carbon dioxide, or blood urea nitrogen was seen in any of the groups.

Values are mean ± SD.

Maternal hypotension. The influence of maternal hypotension on pH, plasma glucose, and blood lactate are shown in Table IV. Nine patients (28%) developed hypotension: six in group 1, two in group 2, and one in group 3. In comparison with the group that remained normotensive, the hypotensive group of patients had a significantly lower maternal vein pH at delivery as well as a lower pH in the umbilical cord vein and artery. Because the hypotensive patients included a greater proportion from the glucose group, this group also had elevated plasma glucose and blood lactate levels in the maternal vein at delivery and in the umbilical cord. In addition, all of these patients had received ephedrine for the correction of hypotension.

Because of these differences in plasma glucose and blood lactate in the hypotensive group, the influence of maternal hypotension was examined within group 1 alone. When the six hypotensive patients were compared with six normotensive patients in group 1, there were no significant differences in the pH, plasma glucose level, or blood lactate level. The glucose concentration in the maternal venous blood at delivery tended to be higher, although not significantly so, in the hypotensive group, possibly because of ephedrine administration.

Uterine incision–to–delivery interval. In order to examine the effects of a prolonged uterine incision–to–delivery interval, patients with a uterine incision–delivery interval >180 seconds were compared with patients with a uterine incision–delivery interval of <180 seconds. A prolonged uterine incision–to–delivery interval did not significantly alter any of the parameters measured.

Comment

The purpose of this study was to evaluate the maternal and fetal metabolic effects of three commonly used intravenous fluids during delivery. The results

demonstrate that acute glucose infusion before delivery resulted in maternal hyperglycemia, hyperinsulinemia, and an increase in blood lactate. These maternal perturbations were associated with fetal hyperglycemia and hyperinsulinemia, higher fetal blood lactate levels, and lower fetal arterial pH.

The key finding of this study was the lower fetal arterial pH in the glucose-infused group. This increase in blood hydrogen ion concentration was accompanied by a significant rise in blood lactate, an increase in carbon dioxide, and a decreased fetal hemoglobin oxygen saturation. An explanation for this lactic acidosis may be obtained from animal data. In chronically catheterized ewes, direct glucose infusion to the fetus can induce an acceleration of the fetal metabolic rate and fetal oxygen consumption.[7] The increase in fetal oxygen consumption has been speculated to be responsible for the decrease in fetal arterial oxygen content. Robillard et al.[5] have shown that chronic fetal hyperglycemia in sheep induces a similar state of fetal arterial hypoxia, metabolic acidosis, and fetal death. Direct infusion of insulin to the fetus caused an increased glucose uptake by the fetus and a decreased fetal arterial oxygen content.[8, 9] Crandell et al.[16] showed that in chronically catheterized ewes hyperglycemia resulted not only in fetal hypoxemia and acidemia but also in a redistribution of the fetal combined ventricular output and a decrease in umbilical blood flow to the placenta. Although there was no significant change in oxygen delivery to the fetal heart, brain, or kidneys in this study, there was a marked decrease in fetal arterial oxygen saturation. On the basis of these studies in animals, one may speculate that acute maternal glucose infusion in human pregnancy results in an increased metabolic rate of the fetus. Glucose consumption and lactic acid production are increased. Fetal oxygen consumption is also increased and results in a decrease in fetal oxygen content and subsequent fetal hypoxemia. Fetal hypoxemia leads to a decrease in pH and, if severe, lactic acidosis. Redistribution of fetal cardiac output may be a compensatory adaptation to these metabolic changes.

This study also examined other metabolic consequences of acute glucose infusion. Acute maternal hyperglycemia persisted more than 40 minutes after the infusion so that, by delivery, the maternal glucose remained elevated and the concentration of blood lactate had doubled. The umbilical cord vein and artery blood lactate concentrations remained twice as high as those of the control group. In contrast, the group that received the Ringer's lactate (28 mEq/L of lactate) did not demonstrate this altered metabolic lactic acidosis.

Other perinatal factors, such as maternal position, maternal hypotension, and surgical time intervals at the time of cesarean section, were examined since these factors are known to influence fetal acid-base status at delivery.[9-13] All patients in this study had left lateral uterine displacement to avoid the effects of aortocaval compression. Maternal hypotension was rapidly corrected and did not influence neonatal acid-base status when controlled for glucose concentration. In this study, a prolonged skin-to-delivery interval did not influence the neonatal acid-base balance. Similar results have been reported with spinal anesthesia in the absence of hypotension.[11] The uterine incision–to–delivery interval also did not appear to influence the pH although there were only a few cases with a prolonged interval of >3 minutes. Therefore, by controlling for these confounding variables, the alterations in substrates and lower pH were attributed to the metabolic effects of acute glucose infusion alone.

In summary, short-term maternal administration of glucose before delivery is associated with fetal hyperglycemia, hyperinsulinemia, an increase in lactic acid, and a significant decrease in pH. Nevertheless, no obvious detrimental effects were observed on the mother, fetus, or neonate in this study. However, these metabolic changes occurred in normal patients at term without any signs of fetal distress or acidosis during the infusion, epidural anesthesia, or surgery. Since fetal distress and acidosis may occur during labor and delivery, acute glucose infusion in this clinical setting may exaggerate the metabolic acidosis associated with fetal distress. When intravenous fluids are necessary in obstetrics, either for hydration or administering medications, large amounts of glucose should be avoided.

We thank Ms. Darlene Spagnoli, Ms. Monica Bakaitis, and Ms. Ellen Brown for their technical assistance, Ms. Sue Fitz for patient recruitment, and Sharon Anthony, R.N., and the Perinatal Clinical Research Center staff for their assistance with patient care.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

The use of fetal neuromuscular blockade during intrauterine procedures

Kenneth J. Moise, Jr., M.D., Robert J. Carpenter, Jr., M.D., Russell L. Deter, M.D., Brian Kirshon, M.D., and Sal F. Diaz, M.D.

Houston, Texas

Advances in fetal therapy have led to the utilization of such techniques as intravascular transfusion of the Rh-affected fetus, bladder shunt placement in the fetus with obstructive uropathy, and percutaneous umbilical blood sampling. Fetal movement makes these procedures technically more difficult while increasing the risk of fetal injury. However, maternal sedation rarely results in adequate suppression of fetal activity. Thus we tested the sedative effects of intramuscular *d*-tubocurarine (3 or 1.5 mg/kg) or pancuronium bromide (0.3 mg/kg) injected into the fetal gluteal region under ultrasound guidance in conjunction with 70 invasive in utero procedures. Short-term paralysis of the fetus was induced in all cases. No deleterious effects of this technique were noted on initial examination of the neonates. Neuromuscular blockade was found to be a very useful adjunct to both diagnostic and therapeutic procedures involving the fetus. (Am J Obstet Gynecol 1987;157:874-9.)

Key words: Fetus, *d*-tubocurarine, pancuronium bromide, fetal paralysis

In utero fetal therapy began in 1963 with the report by Liley[1] of the first successful intraperitoneal transfusion for severe rhesus alloimmunization. Later, Bang et al.[2] used ultrasound-guided needle placement to perform fetal intravascular transfusions. The fetus has now become the target of numerous invasive diagnostic and therapeutic maneuvers that range from percutaneous umbilical blood sampling[3] to placement of intravesical shunts.[4] Fetal movement makes these procedures technically more difficult and may increase the likelihood of trauma to the umbilical vessels or injury to the fetus. Efforts to suppress fetal activity by maternal sedation often meet with only partial success. Using ja combination of meperidine, prochlorperazine, and diazepam, Berkowitz et al.[5] reported that the fetus dislodged the needle in 11% of the intravascular transfusions in their series. Ch. de Crespigney et al.[6] were the first to use intramuscular *d*-tubocurarine to achieve fetal paralysis before intravascular transfusion. Our purpose is to describe our experience with fetal neuromuscular blockade used in conjunction with invasive in utero procedures.

Material and methods

Patients. Between June 1985 and March 1987, neuromuscular blocking agents were used in conjunction with 70 procedures involving 31 fetuses at the Prenatal Diagnostic Center, Baylor College of Medicine, Houston, Texas. In 13 cases two separate procedures were undertaken while the fetus was paralyzed (fetal blood sampling followed by either intraperitoneal transfusion or combined intravascular and intraperitoneal transfusions). The types of procedures and gestational ages when fetal paralysis was used are shown in Table I. Fetal paralysis was used five times in two fetuses, four times in two fetuses, three times in three fetuses, twice in six fetuses, and once in 18 fetuses.

Method of procedure. Fetal weight was calculated by use of the ultrasound parameters of biparietal diameter and abdominal circumference.[7] If ascites were present, the 50th percentile weight for the corresponding menstrual age was used. In the first 44 procedures, an undiluted concentration of 3 mg/ml of *d*-tubocurarine was used to administer a dose of 3 mg/kg estimated fetal weight (group 1). In four subsequent cases the dose was reduced to 1.5 mg/kg (group 2). In the last 12 cases, an undiluted concentration of 1 mg/ml of pancuronium bromide was used to administer 0.3 mg/kg of the estimated fetal weight (group 3). The fetal lie was then assessed with ultrasound. If the fetus was felt to be in a poor position for a particular procedure (e.g., fetal spine anterior for an intraperitoneal transfusion), an attempt was made to improve the position by external manipulation before the institution of fetal paralysis. The fetal femur closest to the anterior uterine wall was localized with real-time ultrasound. A 25-gauge spinal needle was then guided into the fetal gluteal region and the neuromuscular agent was injected. Correct placement was confirmed by the appearance of an echo-

genic area in the fetal thigh (Figs. 1 and 2). Fetal activity was monitored with continuous real-time ultrasound until no limb movement could be detected. The latency period of a particular drug or dosage was defined as the interval from its injection to the cessation of fetal movement. Most patients were discharged before spontaneous reversal of the neuromuscular blockade. Patients were asked to record the time when they first perceived fetal movement. The duration of action of a particular neuromuscular drug or dosage was defined as the time interval between injection and maternal perception of the return of fetal movement.

Results

General experience. Fetal paralysis was achieved in all fetuses. A second injection of an agent was required in 10 cases, probably because of poor placement of the drug. In these cases, the lack of an echogenic area in the fetal gluteal region or the lack of resistance during injection was observed, indicating intra-amniotic placement of the drug.

The mean latency period for the various treatment groups was as follows: Group 1, 3.2 minutes (range 1 to 15 minutes); group 2, 5.1 minutes (range 4 to 6.5 minutes); and group 3, 3.8 minutes (range 1.5 to 16 minutes). The last eight patients in group 1 and all patients in groups 2 and 3 were asked to record the time when they first perceived the return of fetal movement. The mean duration of *d*-tubocurarine action in group 1 was 9.0 hours (range 4.7 to 16 hours) and was 3.8 hours (range 2 to 4.8 hours) in group 2. The mean duration of action of pancuronium bromide (group 3) was 6.8 hours (range 2 to 11.5 hours).

The mean interval between fetal paralysis and delivery was 41 days (range 5 hours to 147 days). Two pregnancies were electively terminated after chromosomal abnormalities were confirmed by fetal blood sampling. One in utero death occurred in a severely hydropic

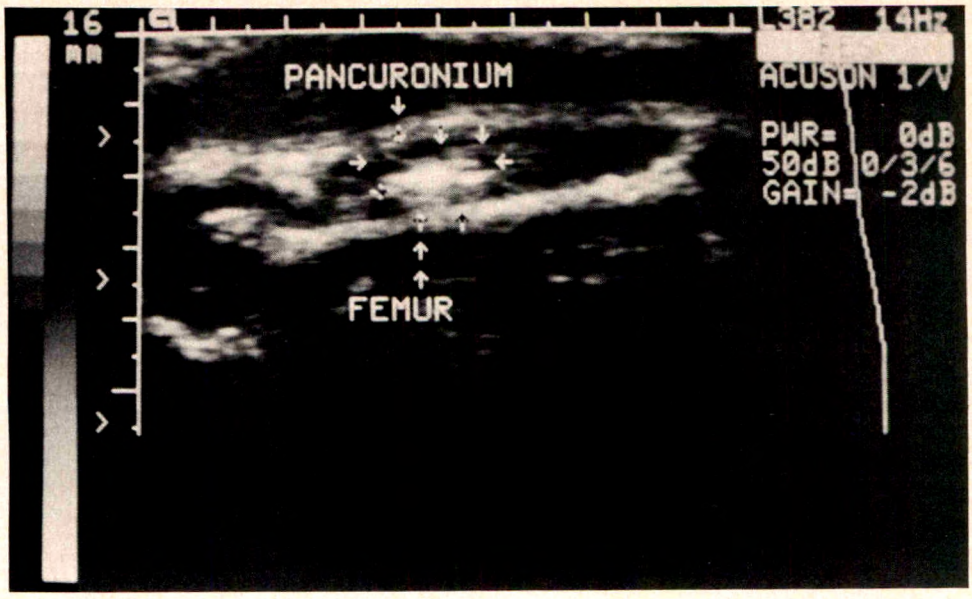

Fig. 2. Fetal gluteal region after injection of pancuronium bromide.

fetus at 22.4 weeks' gestation after intrauterine transfusion for rhesus alloimmunization. Two infants died in the immediate neonatal period. One of these infants was delivered at 28 weeks' gestation because of chorioamnionitis that developed after an intrauterine transfusion for rhesus disease. The infant died secondary to severe hyaline membrane disease. The second infant was delivered by emergency cesarean section at 33 weeks' gestation after abruptio placentae and died as a result of the asphyxial insult. Of the remaining 26 fetuses, three are currently undelivered. The remaining 23 infants were live born and showed no evidence of ill effects secondary to in utero fetal paralysis.

Special cases

Case 1. A 21-year-old woman, para 1-0-0-1, was scheduled to undergo a second intravascular transfusion at 37 weeks' gestation due to rhesus alloimmunization. Amniotic fluid analysis several days before the procedure revealed lack of fetal pulmonary maturity. Estimated fetal weight was 3000 gm. The calculated dose of *d*-tubocurarine for fetal neuromuscular blockade was 9 mg (3 ml of a 3 mg/ml concentration). This volume was felt to be too large for intramuscular injection into the fetal gluteal region. A 0.3 mg/kg dose of pancuronium bromide (total volume 0.9 ml) was thus used. Cessation of fetal movement occurred after 2 minutes and lasted 2 hours. A successful intravascular transfusion was performed without incident.

Case 2. A 25-year-old woman, para 2-0-0-2, underwent an initial intravascular transfusion for fetal hydrops secondary to Kell alloimmunization. Fetal neuromuscular blockade was not instituted because of the large anterior placenta that precluded easy access to the fetal thigh and the relative lack of fetal movement. The procedure needle was guided through the anterior placenta into the umbilical cord insertion without difficulty. Several minutes after the start of the transfusion, the fetus was noted to become very active. Fetal movement against the cord insertion site resulted in displacement of the transfusion needle through the vessel wall. Active bleeding into the amniotic cavity was seen and the needle was immediately withdrawn. The bleeding from the puncture site subsided without evidence of fetal bradycardia.

Case 3. A 31-year-old woman, para 0-0-3-0, was noted to have evidence of fetal hydrops at 34 weeks' gestation. A large right-sided pleural effusion with resulting displacement of the mediastinum against the left chest wall was present. Amniotic fluid analysis revealed borderline pulmonary maturity study results. After the administration of steroids, cesarean section was to be undertaken. After consultation with the neonatology service, a decision was made to perform in utero thoracentesis before delivery to minimize resuscitative efforts at delivery. Pancuronium bromide, 0.3 mg/kg, was administered into the fetal gluteal region. Fetal neuromuscular blockade was complete 3 minutes later. A successful thoracentesis was undertaken, and 120 ml of fluid was removed. A cell count on the fluid revealed a total white blood cell count of 1100 cells/mm^3, consisting of 90% lymphocytes. This finding was felt to be consistent with a congenital chylothorax. After 4 hours, ultrasound revealed vigorous fetal limb movement and cesarean section was performed. The neonate was given 1- and 5-minute Apgar

scores of 9 and 9 and exhibited spontaneous respirations and limb movement at birth. The early neonatal course was complicated by hyaline membrane disease. The infant began oral feedings with a medium-chain triglyceride formula on the seventh day of life. Serial chest radiographs demonstrated resolution of the right-sided pleural effusion. Discharge occurred on the nineteenth day of life.

Comment

Tubocurarine was the first agent used for fetal neuromuscular blockade.[6] Ch. de Crespigney et al. arbitrarily chose a dose of 3 mg/kg, which represents a tenfold increase in the usual recommended intravenous dose for neonatal anesthesia.[8] In the original report the drug was administered and then followed 30 minutes later by intravascular transfusion.[6] The fetus was not monitored by ultrasound during the interim; therefore the latency period of the drug was not known. Our initial experience with the drug indicated that its onset of action was rapid (mean time 3.3 minutes). When we used the 3 mg/kg dose described by Ch. de Crespigney et al., we noted that the fetus remained paralyzed for a prolonged period (mean 9 hours). The duration of action of the drug was felt to be excessive. In an effort to reduce the length of fetal paralysis, we used a 50% reduction in the dose of *d*-tubocurarine. This resulted in a slight prolongation of the mean latency period (from 3.2 to 5.1 minutes) before the onset of fetal neuromuscular blockade. More importantly, the duration of fetal neuromuscular blockade was reduced by more than half (mean 3.8 hours).

When faced with a need for fetal paralysis in the first case described, we decided to select an alternative agent to *d*-tubocurarine. The pharmacology of the various neuromuscular agents was considered in the selection of a new agent for fetal neuromuscular blockade. Three agents are currently in popular use: vecuronium, atracurium, and pancuronium bromide. Vecuronium is excreted primarily by the liver and would be suboptimal for use in the Rh-affected fetus, because the liver may be involved in extrahematopoietic red cell production.[9] Atracurium is metabolized in the vascular space through Hoffman degradation and ester hydrolysis.[10] Although these two agents are reported to have minimal cardiovascular effects, their short half-life was felt to be a disadvantage when extended in utero procedures are planned.[10] Renal excretion serves as the primary mode of elimination for pancuronium bromide,[10] while hepatic metabolism with excretion into the biliary tree is an alternative route of excretion.[10] Pancuronium bromide would therefore represent an agent with little potential for drug-related hepatic toxicity. Considerable experience has been gained with this drug in neonates. It is noted to be approximately five times more potent than *d*-tubocurarine, allowing its use in very small volumes.[11] We calculated a dose of 0.3 mg/kg based on the 1.5 mg/kg dose of *d*-tubocurarine used in our second group of fetuses. Pancuronium bromide was noted to have a rapid onset of action (similar to 3 mg/kg of *d*-tubocurarine), with a duration of fetal neuromuscular blockade intermediate between the 1.5 and 3 mg/kg *d*-tubocurarine doses. This length of fetal paralysis was felt to be adequate to perform even the most difficult intravascular exchange transfusion. Recently, Seeds et al.[12] have reported the use of intramuscular pancuronium bromide in six cases of fetal neuromuscular blockade. In all cases cessation of fetal movement had occurred by 1 minute after injection, with return of movement by 2 hours. These authors did not calculate the dose of pancuronium bromide based on fetal weight but instead used a standard dose of 0.5 mg. The oldest fetus in their series was 31 weeks' gestation and would have a fiftieth percentile estimated fetal weight of 1630 gm.[13] Based on a dose of 0.3 mg/kg, we would have administered 0.49 mg of pancuronium bromide as compared with the 0.5 used by Seeds et al. Calculation of a dose based on fetal weight would seem to follow sound pharmacologic principles and would allow the use of doses <0.5 mg for fetal neuromuscular blockade at earlier gestational ages.

Although neuromuscular blocking agents are usually administered to the neonate by the intravenous route, we chose to follow the protocol of Ch. de Crespigney et al.[6] and use the intramuscular route of administration. The intramuscular route offers several advantages over the intravenous approach: (1) fetal neuromuscular blockade can be induced before umbilical vessel puncture for transfusions or percutaneous umbilical blood sampling, enabling easier placement of the needle after the cessation of fetal movement; and (2) fetal neuromuscular blockage effected in this manner allows for fetal paralysis in conjunction with such procedures as fetal skin biopsy, in which access to the fetal vascular space is not part of the usual procedure. Disadvantages of intramuscular injection in the fetus include the need for a second amniotic puncture and the risk of possible injury to structures in the fetal thigh. Seeds et al.[12] used a 22-gauge needle for the intramuscular injection of pancuronium bromide. We have found a 25-gauge needle to be more than adequate for this technique and feel that the smaller needle should theoretically reduce the incidence of complications. To date, no evidence of gluteal hematomas or nerve injury has been noted in any of the neonates in our series of fetal neuromuscular blockade.

Indications for the use of fetal paralysis are varied. Umbilical vessels near the placental cord insertion are

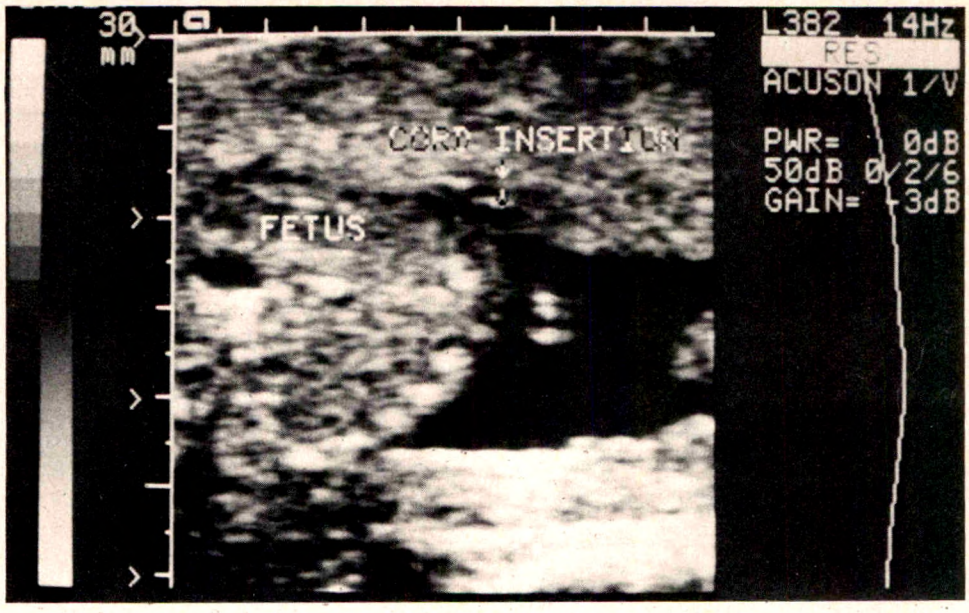

Fig. 3. Fetus obscuring the cord insertion of an anterior placenta.

probably the most commonly used sites for intravascular fetal transfusion.[5, 14] In cases of posterior placentation, fetal movement may result in dislodgement of the needle once it has been placed. In addition, the fetal lie may obscure the posterior cord insertion, making use of this site technically impossible. Attempts to puncture the vessels in a floating loop of umbilical cord are equally difficult. The intrahepatic portion of the umbilical vein or the cord vessels at the fetal umbilicus have been used by some investigators to circumvent these problems.[2, 5, 6] If the hydropic fetus is moribund, these sites may be relatively safe due to the lack of fetal activity. Nonetheless, fetal movement may increase in response to the acute correction of anemia, placing the fetus at risk for vessel trauma. The use of neuromuscular blockade in the fetus would therefore appear to be very advantageous when intravascular transfusion is undertaken with a posterior placentation.

If an anterior placentation is present, puncture of the umbilical vessels is usually technically easier. In this situation, one may question the need for fetal paralysis. Although the needle will not usually enter the amniotic cavity if the cord root is approached on end, occasionally the needle may puncture the cord a short distance from the actual insertion, resulting in a short segment of needle in the amniotic cavity. Fetal movement near the cord insertion may result in difficult visualization of the umbilical vessels (Fig. 3). Our second case illustrates that fetal movement against the cord insertion site can result in displacement of the needle through the vessel wall, with the potential for severe trauma to the umbilical vessels. For this reason, we would advocate the use of fetal paralysis for all intravascular transfusions even if the placenta is located anteriorly.

Fetal movement during intraperitoneal transfusion may place the fetus at risk for internal visceral injury. Bowman and Manning[15] have advocated the placement of intraperitoneal catheters to decrease the length of time the needle remains in the fetus. Fetal paralysis enables the proper placement of the needle followed by unhurried transfusion of blood, negating the need for catheters.

Percutaneous umbilical fetal blood sampling can be technically difficult during one's initial experience. Although we no longer use fetal neuromuscular blockade during percutaneous umbilical blood sampling, we found it to be very useful in our earlier cases. After one masters the technique of umbilical cord sampling, fetal paralysis may no longer be warranted. Occasionally the very active fetus will make puncture of a posterior cord insertion technically difficult. In these cases, the use of a neuromuscular agent would substantially increase the ease of the procedure.

Finally, we have found fetal paralysis to be beneficial during such procedures as paracentesis, thoracentesis, skin biopsy, and shunt placement.

Several minor disadvantages of fetal neuromuscular blockade merit discussion. The latency period after injection of the drug is usually several minutes. During this period the fetus may assume a position that would make a particular procedure very difficult. Manipulation of the fetus can be attempted, but we advocate that this be done cautiously. The lack of muscle tone secondary to fetal paralysis could potentially place the fe-

tus at risk for iatrogenic skeletal injury. Changes in fetal posture may also occur after neuromuscular blockade of the fetus. On several occasions, marked flexion of the fetal spine and extremities (a "balled-up" position) made access for intraperitoneal transfusion difficult. Another potential disadvantage to fetal neuromuscular blockade would occur if emergency delivery must be effected secondary to fetal distress during a procedure. A paralyzed infant would be delivered. Atropine and neostigmine could be administered in an attempt to reverse the fetal paralysis; however, these agents are not likely to be effective if spontaneous resolution of fetal paralysis is not present.[16] Our experience has shown that the duration of fetal neuromuscular blockade after intramuscular injection of *d*-tubocurarine or pancuronium bromide indicates that endotracheal intubation and assisted ventilation for several hours after birth would be necessary. Our third case illustrates that fetal neuromuscular blockade can, however, be used just before scheduled delivery if sufficient time is allowed for spontaneous recovery.

Although we have found fetal neuromuscular blockade to be an invaluable adjunct to invasive in utero procedures, the long-term effects of neuromuscular blocking agents in the fetus have not been studied. Neuromuscular blockade of the fetus is a short-lived effect and would not be expected to have subsequent detrimental consequences. Prospective evaluation of these infants is ongoing at our institution.

Fetal assessment based on fetal biophysical profile scoring: Experience in 19,221 referred high-risk pregnancies

II. An analysis of false-negative fetal deaths

F. A. Manning, M.D., I. Morrison, M.B., C. R. Harman, M.D., I. R. Lange, M.B., and S. Menticoglou, M.D.

Winnipeg, Manitoba, Canada

The incidence of false-negative fetal death, which is defined as stillbirth unrelated to major anomaly or alloimmunization occurring after a last normal fetal biophysical score, was determined in 19,221 referred high-risk pregnancies. The calculated rate of fetal death after a last normal test was 0.726/1000 (14 deaths), which remained relatively constant despite a progressive increase in tests and patients studied. We conclude that a normal fetal biophysical profile score confers a high probability of perinatal survival. (AM J OBSTET GYNECOL 1987;157:880-4.)

Key words: Fetal biophysical profile, stillbirth, false-negative test

Fetal biophysical profile scoring is a method of antepartum fetal risk assessment based on a dynamic ultrasound survey of biophysical variables.[1] According to the experience reported from our center and other independent clinical laboratories, the method when applied to a high-risk obstetric population yields a reduction in the perinatal mortality rate.[2-4]

One unique characteristic of the testing method is the high proportion of normal test results, which has been reported as 97.5% among 30,411 tests.[2, 3] Paradoxically, this high rate of normal test results could be the result of either high- or low-negative predictive accuracy of the testing method. The prevalence of perinatal disease, as defined by the sharpest end point, perinatal death, is low even among the selected high-risk population; conversely, the expectation of live birth is high. A testing method of high negative predictive accuracy applied to this population would therefore yield a high proportion of normal results, mirroring the population expectation. Conversely, a test of lesser negative predictive accuracy by which the compromised fetus may be assigned a normal test result could also yield the same high proportion of normal test results. Resolution of this issue as it pertains to fetal biophysical profile scoring is of considerable clinical importance. Accordingly, we have reviewed our experience with this testing method in 19,221 referred high-risk pregnancies. The purpose of this retrospective study was twofold: to catalog all false-negative fetal deaths by number and associated etiologic factors and to calculate the probability of a fetal death within 1 week of a last normal fetal biophysical profile score.

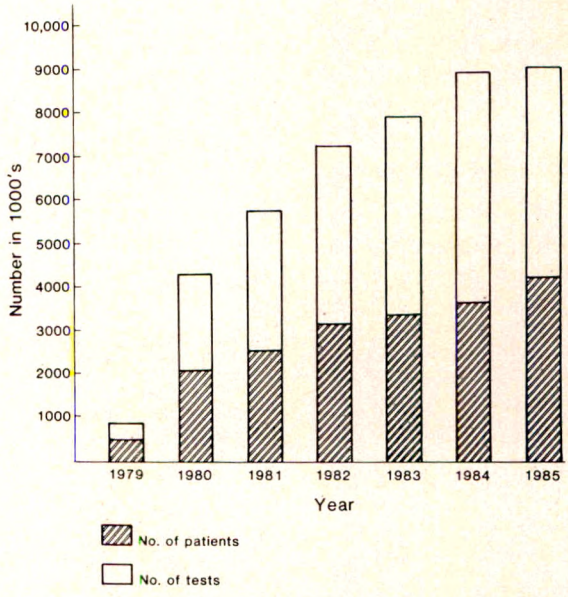

Fig. 1. The annual distribution of the number of patients referred for fetal biophysical profile scoring and the number of tests performed.

Table I. Biophysical profile scoring: Management protocol

BPS score	*Interpretation*	*Recommended management*
10	Normal nonasphyxiated	No fetal indication for intervention; repeat test weekly except in diabetic patient and postdate pregnancy (twice weekly)
8/10 normal fluid 8/8	Normal nonasphyxiated fetus	No fetal indication for intervention; repeat testing as per protocol
8/10 decreased fluid	Chronic fetal asphyxia suspected	Deliver
6	Possible fetal asphyxia	Deliver if AFV abnormal, if normal fluid at >36 wk with favorable cervix delivery; if ≤36 wk or L/S <2/1 or cervix unfavorable; repeat test in 24 hr; if repeat test ≤6 deliver; if repeat test >6 observe and repeat per protocol
4	Probable fetal asphyxia	Repeat testing same day; if BPS ≤6 deliver
0-2	Almost certain fetal asphyxia	Deliver

BPS = Biophysical profile scoring; AFV = amniotic fluid volume; L/S = lecithin/sphingomyelin ratio.

Table II. False-negative deaths and probability of fetal death after a normal last fetal biophysical profile score: Annual distribution

Study yr	*No. of patients (total)*	*No. of fetuses with last normal test*	*% of total patients*	*No. of false-negative deaths*	*Probability of false-negative fetal deaths/1000 patients*
1979-80	2586	2514	97.21	2	0.795
1981	2596	2526	97.3	2	0.791
1982	3199	3106	97.1	2	0.644
1983	3336	3249	97.4	2	0.555
1984	3751	3631	96.8	3	0.826
1985	4388	4265	97.2	3	0.703
Total	19856	19291	97.15	14	0.726

Method

Fetal biophysical profile scoring was the sole method used for fetal risk assessment in this study. The biophysical profile scoring is derived from the assessment of five variables (fetal movement, tone, breathing, qualitative amniotic fluid volume, and heart rate acceleration with fetal movement), which are coded as normal or abnormal according to fixed criteria and are then assigned an arbitrary score of 2 if normal and 0 when abnormal.[1] For the purpose of this ongoing study, a score of 8 or 10 was considered normal. A biophysical profile scoring of 8 was achieved in two ways: either four or five variables were normal, or more recently, if the first four variables monitored by dynamic ultrasound methods (movement, tone, breathing, and qualitative amniotic fluid volume) were normal. The latter modification has been studied prospectively and is found not to alter the predictive accuracy of the testing method.[5] When the test score was normal, it has been our consistent policy to advocate conservative therapy.[2] Exceptions to this policy are fetuses with a normal score and postdate pregnancies with a favorable cervix, growth-retarded fetuses with proved pulmonary maturity and a favorable cervix, insulin-dependent diabetic patients at 37 weeks or greater and proved pulmonary maturity, class A diabetic patients at term with a favorable cervix, patients with a previous abdominal delivery of a recurrent etiology and proved pulmonary maturity, and patients with unstable hypertension or other medical disorders that pose a serious threat to maternal health.

The study population was made up of consecutive referred pregnancies categorized as high risk by fixed referral criteria[2] and of at least 26 weeks' gestation. Fetal biophysical profile scores were obtained once weekly for all referred patients, except those with proved or suspected postmaturity (>42 completed weeks) and diabetes. The latter two groups were tested twice weekly. Test scores were used to guide management according to fixed criteria (Table I). The study period encompassed 75 months (1979 to 1985 inclusive).

A false-negative test result was defined as fetal death (stillbirth) that occurred in a structurally normal fetus within 7 days of a last normal test result (biophysical profile scoring = 8 or 10). Structurally normal severe Rh alloimmunized fetuses were excluded from this study population since death in such fetuses was caused by either the alloimmunization process or trauma at the time of therapy. The time of fetal death was determined from either maternal subjective notation of cessation of fetal movement or objective confirmation of the absence of fetal heart rate activity, whichever interval was least.

Table III. Death among structurally normal, nonisoimmunized fetuses within a week of a last normal fetal biophysical profile score

Case No.	*Initials*	*Referral risk factor*	*Fetal age at referral (wk)*	*No. of tests*	*Fetal age last test (wk)*
1	M. W.	Severe hypertension	27	3	28
2	F. H.	Peripheral vascular disease, myocardial infarction	27	4	29
3	G. T.	AP hemorrhage	28	2	30
4	L. S.	Sickle cell disease	30	2	31

13	M. M.	Hypertension	38	1	38
14	L. C.	Postdates	42½	1	42½

IUGR = Intrauterine growth retardation; AP = antepartum; IP = intrapartum; NST-R = reactive nonstress test.

Results

During the 75-month study period, 44,828 biophysical profile scoring results were recorded among 19,221 referred high-risk pregnancies. Considering multiple gestation, a total of 19,856 fetuses were studied. The primary indication for initial referral remained unchanged from previous reports[2] with the major indications being suspected intrauterine growth retardation (22.8%), hypertension (16.5%), postdate pregnancies (11.9%), and diabetes (9.4%). Both the number of patients and tests have increased annually, but the average number of tests per patient has remained relatively constant (Fig. 1). The mean fetal age at initial referral was 34 weeks (range, 26 to 44 weeks).

In total 44,828 fetal biophysical profile scores were recorded, 43,887 of which were normal (97.9%). A last normal test score was normal in 19,291 (97.15%) of the fetuses tested. Fourteen fetal deaths caused by factors other than major anomaly or alloimmunization were recorded. Therefore the probability of false-negative fetal death occurring within 1 week of a last normal fetal biophysical profile score was 0.726/1000 live births. This probability of false-negative fetal death varied on an annual basis, ranging from as low as 0.550/1000 to 0.826/1000 and did not change in accordance with the progressive increase in patients tested (Table II).

Clinical details of these 14 deaths, which are listed according to gestational age at initial referral, are given in Table III. Several points warrant additional comment. The mean interval between last test and fetal death was 4.43 days (range, 1 to 7 days), with two of 14 fetuses dying within 24 hours of a normal test result. Ten of the 14 fetuses had more than one normal score a week before the final test.

Four of the 14 deaths occurred during the intrapartum period. Two fetuses had continuous electronic fetal monitoring that documented evidence of fetal compromise. In one case (case 14) fetal distress was reported, but action was not taken for reasons that are unclear. In the other (case 13), chorioamnionitis was not treated in labor and the response to fetal distress was delayed. The other two intrapartum deaths followed overt cord prolapse.

Eight of 14 deaths (57.2%) occurred in the absence of recognized subsequent risk factors and are assumed to be the result of chronic asphyxia undetected at the time of testing; four of these deaths were associated with proved intrauterine growth retardation. The gestational age at which death was diagnosed ranged from 27 to 36 weeks. The mean birth weights were 1460 gm for the four fetuses with intrauterine growth retardation and 1622 gm for the other four. In the final two false-negative deaths, hypoxemic maternal deterioration (case 4) and acute placental abruptio (case 8) led directly to fetal demise, which was not predicted by biophysical profile scoring.

Two of the 14 mothers were diabetic, and four had diastolic blood pressure exceeding 90. There is no apparent relationship between risk factors prompting referral and the risk of false-negative fetal death in this group, of which the proportions for each category are similar to the entire referral population. Overall there is no apparent relationship between fetal age at last test and the risk of false-negative fetal death; the values ranged from 28 to 42½ weeks.

Comment

The end points used to judge test accuracy are variable. In this study we have used fetal death as the end

Last test result	*Interval test-death (days)*	*Birth weight (gm)*	*Time of death*	*Cause of death*
8/8	1	540	AP	Asphyxia unexplained, proved IUGR
8/8	3	830	AP	Asphyxia, unexplained
8/8	7	1100	AP	Asphyxia, unexplained
8/8	1	2200	AP	Maternal hypoxemia, sickle cell crisis
8/8	3	2160	IP	Acute asphyxia, cord prolapse at home
10 (NST-R)	4	1100	AP	Asphyxia, unexplained
8/8	7	2126	AP	Asphyxia, unexplained, associated IUGR
8/8	7	980	AP	Asphyxia, abruption, probable IUGR
8/8	7	1700	AP	Asphyxia, unexplained, associated IUGR
8/8	3	1470	AP	Asphyxia, unexplained, associated IUGR
10 (NST-R)	5	2480	AP	Asphyxia, unexplained
8/8	5	3920	IP	Acute asphyxia, cord prolapse
10 (NST-R)	5	3650	IP	Fetal distress, chorioamnionitis, fetal pneumonia
8/8	4	3400	IP	Fetal distress in labor, not treated

point, since unlike measures of morbidity this selected end point is not subject to interobserver variability or observer bias. We assume a relationship between the incidence of death and morbidity in a given study population, but this point was not specifically addressed in this study.

The calculated negative predictive accuracy for this biophysical profile scoring method was 99.224%; the reciprocal, that is, the probability of fetal death after a last normal test result, was 0.726/1000 patients. Therefore the high proportion of normal test results recorded with this method may be attributed to high negative predictive accuracy.

The ability to predict continued fetal survival for a finite interval has major clinical implications for both the mother and fetus. The art of obstetrics is based on the balancing of risks. For the high-risk pregnancy, this balance is usually between conservative management and the attendant risk of stillbirth and intervention with the attendant risks of prematurity complications and an increased probability of operative delivery. The high probability of continued fetal survival when the biophysical profile score is normal can be of major importance in reaching the appropriate management decision. Application of this concept to a specific high-risk population, postdate pregnancies, has been shown to reduce both fetal and maternal risks.[6]

The probability of fetal death after a last normal test, although low, would have been reduced even further under ideal conditions. The two cases of fetal death caused by cord prolapse would now be considered as ideally preventable in light of a recent report of an accurate antepartum method for the diagnosis of this condition.[7] It seems reasonable to assume that more aggressive intrapartum care would have prevented the deaths that occurred in labor. Therefore under the most ideal circumstances, the occurrence of false-negative fetal death could have been reduced to 0.518/1000 (10 deaths).

The perfect antepartum testing method would yield no false-negative deaths. Our cumulative experience with fetal biophysical profile scoring indicates that this test falls short of the ideal. An understanding of the basis for test failure is important to plan for either modification of the existing method, addition of ancillary variables, or both. The existing method is designed to evaluate fetal health at the time of assessment from which a statistical probability of continued fetal health may be constructed. The superimposition of either chronic deterioration in maternal or fetal condition or acute variables affecting condition will affect the accuracy of the testing method. The former constraint would be overcome by more frequent testing, but as shown in case 4, this modification would not prevent all false-negative deaths. Furthermore, whether the increased workload would be justified by a lower false-negative fetal death rate remains untested. Nonetheless, based on this experience we have now begun more frequent testing in the immature fetus with ultrasound-determined growth failure and have added proteinuric, hypertensive disorders to the indications for twice weekly biophysical profile scoring.

Recognition of premonitory signs of acute asphyxia would be a key step in improving test accuracy. The potential value of antenatal diagnosis of cord presentation is obvious. A method for the detection of impending abruption would be a great value. In this series one fetal death (case 8) and possibly at least one other death (case 1) might have been avoided by such information. The diagnosis of "abruption in evolution" by ultrasound methods is reported, but the field remains largely unexplored.[8]

We conclude from these data that a normal fetal biophysical profile score confers a high probability of subsequent fetal survival. In the clinical setting it would seem reasonable, based on these data, to continue conservative management of the immature fetus or the mother in whom delivery may not be accomplished with ease when the biophysical profile score is normal.

Acute oligohydramnios in postdate pregnancy

Daniel Clement, M.D., Barry S. Schifrin, M.D., and Richard B. Kates, M.D.

Tarzana, California, and Spokane, Washington

The evaluation of amniotic fluid volume plays a major role in antepartum fetal surveillance. Although the definition of diminished amniotic fluid volume varies, this sign is considered by itself an indication for intervention in the near-term fetus. The interval of testing is predicated on the concept that amniotic fluid volume diminishes slowly (unquantified) as a result of developing hypoxia. We present six postterm pregnancies in which amniotic fluid volume diminished abruptly over 24 hours. Although one fetus died, the three babies delivered by cesarean section and the two babies delivered after a 2-day labor did well, despite obvious postmaturity syndrome, meconium staining, and variable decelerations. Apgar scores in the survivors were above 8, and pH results failed to confirm hypoxia. These data suggest the need to better understand the mechanisms regulating amniotic fluid volume. (Am J Obstet Gynecol 1987;157:884-6.)

Key words: Acute oligohydramnios, postdate pregnancy, fetal surveillance

Oligohydramnios accompanies a broad range of reproductive disorders including anomalies of the fetus and functional disorders of the mother, fetus, and placenta.[1, 2] In nonanomalous fetuses, oligohydramnios may complicate postterm pregnancies and postmaturity syndrome in the newborn infant.

The recognition of these data have prompted some authors[1] to include assessment of amniotic fluid volume in the evaluation of fetal well-being as one of the components of the biophysical profile. Diminished amniotic fluid volume (however defined) generally mandates intervention (delivery) in the near-term fetus, irrespective of the results of other tests in the biophysical profile. Underlying this approach is the appealing but unsubstantiated allegation that amniotic fluid volume diminishes slowly (unquantified) in response to hypoxia or other stress and that the amniotic fluid volume will diminish before the fetus deteriorates. The assumption that amniotic fluid volume diminishes slowly has been challenged recently in the report by Weinbaum et al.,[2] who described a patient at 36 weeks of gestation in whom amniotic fluid volume diminished dramatically over 24 hours. We add to this observation by reporting on six women with postdate pregnancies in whom amniotic fluid volume also diminished dramatically over 24 hours.

smokers) had uneventful prenatal courses with normal glucose screening; each weighed well over 100 pounds and had gained weight normally during pregnancy. Each mother was tested initially because of potentially prolonged pregnancy (>287 days from the last menstrual period).

Results

We obtained biophysical profiles on 14 occasions in these six patients. Two patients received three tests; all others had two. In all cases the last two tests were obtained within 24 hours of each other. On the next to last test, four of the six fetuses demonstrated a reactive nonstress test (NST); two were deemed nonreactive. None revealed decelerations. Body movements, breathing movements, tone, and amniotic fluid volume (pocket >2 cm) were normal in each patient. All patients were examined on the following day. The two patients with nonreactive tests were examined as part of a routine follow-up, whereas those with reactive tests were seen because of complaints of decreased fetal movement. In all instances repeat examination revealed diminished and/or absent amniotic fluid volume (pocket <1 cm). In no instance was there evidence of extra amniotic collection of fluid or ruptured membranes. One of the babies with a previously reactive NST was dead; in the other five the NST was reactive, but variable decelerations were present.

On the basis of these findings, all patients had labor induced. Three (including the stillbirth) were delivered vaginally. Two babies were delivered uneventfully 2 days later, after prolonged induction of labor. Meconium-stained fluid and intermittent variable decelerations during labor were evident with these two babies, but they had average variability and reassuring scalp pH values. The three cesarean births were performed on the basis of variable decelerations during induction of labor.

The three male and three female infants ranged in birth weights from 3200 to over 6100 gm. Cord blood gas values were available in four of the five survivors and revealed normal pH values. The 1- and 5-minute Apgar scores for all of the survivors were ≥8. All five babies revealed stigmas of postmaturity syndrome, including meconium staining and evidence of wasting. The hematocrit level in three babies was elevated (>54%). However, all babies pursued normal courses and were discharged home with their mothers.

Comment

Oligohydramnios develops in about 0.5% to 4.0% of pregnancies, depending on the population, the interval between testing and delivery, and the criteria for diminished amniotic fluid volume. Case reports such as these do not permit the calculation of the frequency of acute oligohydramnios, the rate of disappearance of fluid, the volume of amniotic fluid mobilized, or the preexisting amniotic fluid volume. However, these reports may provide insight into the mechanisms of fetal and maternal homeostasis that result in redistribution of water from the fetal compartment. They also raise concerns about the scoring of biophysical parameters, the intervals between antepartum tests, and the value of including amniotic fluid volume as a critical fetal test parameter.

Despite the diminution in amniotic fluid volume, appearance of meconium, variable decelerations, and postmaturity syndrome in the five surviving babies, we found little obvious impact on the condition of the fetus. The cause of death could not be established in the case of the obviously postmature baby. On the basis of the normal antepartum tests 24 hours previously and the known association of oligohydramnios, cord compression (variable decelerations), and fetal distress and/or death, we infer that an abrupt cord accident followed the dramatic reduction in amniotic fluid volume and was the most probable cause of death. It seems unlikely that ongoing asphyxiation or even chronic hypoxia stimulates these dramatic changes in amniotic fluid volume. Indeed, all the surviving fetuses had variable decelerations during antepartum testing and early labor, but normal variability and pH values prevailed after the diminution in amniotic fluid volume, and two babies tolerated 36 to 48 hours of labor satisfactorily. Rayburn and others have previously commented on this syndrome of the nutritionally deprived but otherwise well-oxygenated fetus.

The postmaturity syndrome present in all of these babies draws attention to the fact that the loss of amniotic fluid volume indeed reflects fetal fluid loss. The dynamics of amniotic fluid exchange are complex, and the causes of transfer of water from the fetal to the maternal compartment have yet to be clearly defined. Fetal urine output and swallowing appear to be major determinants of amniotic fluid volume at term, and a number of factors associated with diminished urine production, such as hypoxia, may result in oligohydramnios. Nevertheless, there was little to suggest impaired urine output in any of the newborns reported here.

Studies of uterine and umbilical blood flow by Doppler examination were not available to us. If we are to understand the interrelationships of fetal condition, maternal and fetal blood flow, and amniotic fluid volume dynamics, such comprehensive testing will be necessary. Seemingly, logic dictates that uterine blood flow must be adequate to resorb so much amniotic fluid so quickly.

The scoring system proposed for the biophysical profile gives equal weight (2 points) to each variable (NST, breathing, tone, movement, volume). Advocates of the scoring system generally consider scores of 8 and 10 indicative of fetal well-being, requiring no clinical intervention. The cases reported here and elsewhere suggest that such scoring systems may be misleading. Further, the optimal interval for testing has not been defined. As a minimum, weekly testing seems inadequate in conditions in which the fetus is at risk of oligohydramnios (e.g., postdates or intrauterine growth retardation).

BRIEF SUMMARY

INDICATIONS:
FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS:
FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS:
General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS:
Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION:
Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

Abdominal pregnancy: Magnetic resonance identification with ultrasonographic follow-up of placental involution

Rahima Spanta, M.D., Larry E. Roffman, M.D., Timothy J. Grissom, M.D., James R. Newland, M.D., and Bruce M. McManus, M.D., Ph.D.

Omaha, Nebraska

Abdominal pregnancy is a rare event and preoperative diagnosis may be difficult. Recently, sonographic examination and magnetic resonance imaging have proved helpful in the preoperative diagnosis in a patient who presented with advanced abdominal pregnancy after tubal sterilization. As well, ultrasound was of benefit in the follow-up of placental involution after delivery. (AM J OBSTET GYNECOL 1987;157: 887-9.)

Key words: Abdominal pregnancy, placental involution, ultrasound, magnetic resonance

Abdominal pregnancy is a rare and dangerous obstetric phenomenon. The earliest description of an advanced abdominal pregnancy was recorded nearly one thousand years ago, and operative delivery with survival of mother and baby in such a case was accomplished by a swine gelder in Switzerland in the year 1500.

Preoperative diagnosis is often missed, usually because the rare condition has not been considered. Maternal history may be helpful, and previous pelvic inflammatory disease and ectopic pregnancy, together with abdominal discomfort in the absence of Braxton-Hicks contractions,[1] may be a guide. Sonography, which replaced abdominal film diagnosis, suggests the presence of an intra-abdominal pregnancy when an abnormal relation among fetus, placenta, amniotic fluid, and uterus is noted.[2] However, sonographic interpretation may occasionally be difficult because of distorted pelvic anatomy and/or overlying bowel gas. Recently, magnetic resonance imaging has been used in obstetric diagnosis, providing rather exact information regarding the relationship between the fetus, placenta, amniotic fluid, and uterus.[2]

We have had the opportunity to follow the late course of an abdominal pregnancy that was diagnosed by magnetic resonance imaging at 30 weeks' gestation by menstrual age. In addition, placental involution was characterized by ultrasound during an 8-month period after cesarean delivery of the fetus.

From the Departments of Pathology and Microbiology and Diagnostic Radiology, University of Nebraska Medical Center, and the Department of Obstetrics and Gynecology, Bishop Clarkson Memorial Hospital.

Case report

A 24-year-old, gravida 4, para 3 woman was admitted to the hospital because of an enlarging, uncomfortable lower abdomen. The patient had felt some movement in the lower abdomen. She had had three previous uncomplicated pregnancies, the last delivery occurring 8 months before, after a normal labor and an uneventful puerperium. The patient had a menstrual period about 2 months thereafter, and dilatation, curettage, and laparoscopic tubal sterilization were performed. The patient consulted her physician again when she noted increasing abdominal size and abdominal discomfort.

A pelvic ultrasound evaluation revealed a fetus of approximately 30 weeks' gestation (menstrual age) by measurement of the biparietal diameter. A "mass" separate from the fetus was thought to be the uterus, a finding suggestive but not diagnostic of an extrauterine pregnancy. An x-ray film of the abdomen disclosed a single fetus in a transverse position with the fetal head on the maternal left. Magnetic resonance imaging confirmed the presence of an extrauterine pregnancy primarily on the left with a cephalad attachment of the placenta (Fig. 1). It could not be determined whether this attachment involved bowel, mesentery, omentum, uterus, or a combination. Because of the extrauterine location of the fetus, it was delivered by cesarean section. At operation the transverse position of a male fetus at the L-5 to S-1 level was confirmed. On delivery, Apgar scores were 5 at 1 minute and 8 at 5 minutes. The baby had multiple compressive deformities on the right parietal skull and the right mandible. Neck and chest asymmetry was noted with compressive deformities of the right side as compared with the left. Despite ventilatory support, the infant's pulmonary status deteriorated, and he died 10 days after delivery.

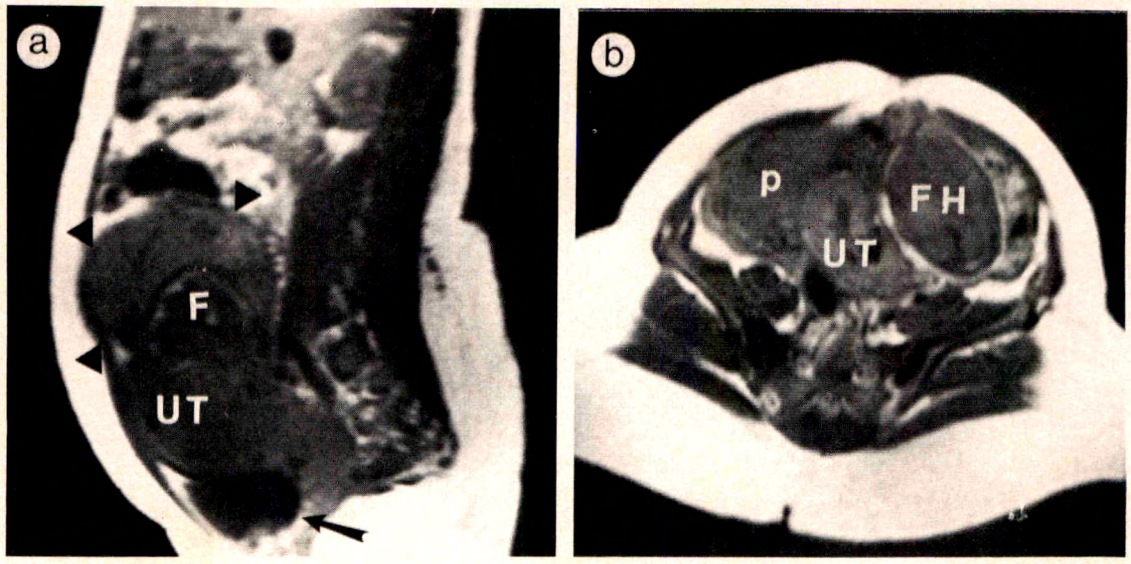

Fig. 1. Prepartum magnetic resonance images of maternal-fetal-placental structures. GE Signa System, 1.5 Tesla, T weight, General Electric. Partial saturation technique with TR of 800 and TE of 25. *a,* Sagittal view of the abdomen illustrating the position of the uterus *(UT)* with respect to the fetus *(F),* placenta *(arrowheads),* and bladder *(arrow). b,* An axial image of the abdomen confirms the relationship between the fetal head *(FH),* a portion of the placenta *(P),* and the uterus *(UT).*

The placenta was attached to the broad ligament, bowel, and mesentery; thus the umbilical cord was ligated proximal to the placenta after delivery of the baby and the placenta was left in situ. Pelvic ultrasonographic examination 2 weeks after delivery showed slight involution and decrease in the size of the placenta. The patient was followed up as an outpatient on a monthly basis with ultrasonography of the placenta to characterize the course of regression in placental size and vascularity. The most recent pelvic ultrasound evaluation 8 months post partum revealed an overall fourfold reduction in placental size since delivery.

Comment

Early abdominal pregnancy is typically self-limited by hemorrhage from trophoblastic invasion with complete abortion of the gestational sac, leaving a discrete crater that is sometimes difficult to identify.[3] Advanced abdominal pregnancies, as in our patient, survive the hemorrhage of trophoblastic invasion and implant secondarily during the first trimester on any adjacent structure.

The clinical picture of abdominal pregnancy is extremely variable, the most frequent signs and symptoms being abdominal pain (100%), vaginal bleeding early in pregnancy, persistent nausea and vomiting, general malaise, and painful fetal movements.[1, 2] A history of an acute, short-lasting episode of abdominal pain in early pregnancy, indicating a "tubal accident," is frequently recorded. Our patient had abdominal pain and experienced painful fetal movements.

Ninety-nine percent of all pregnancies are intrauterine. Of the 1% of pregnancies that are extrauterine, 98% are intratubal, 1% are ovarian, and 1% are primary or secondary peritoneal implants.[3] The primary abdominal type of extrauterine pregnancy is extremely rare. Classification of the primary abdominal pregnancy rests on the following criteria[1]: (1) Both tubes and ovaries are normal, with no evidence of recent or remote injury. (2) There is no evidence of uteroperitoneal fistulas. (3) The pregnancy is adherent to the peritoneal surface without evidence of secondary implantation after a primary nidation in the tube. In light of the tubal ligation performed 32 weeks before the cesarean delivery and apparently 2 weeks before implantation in our patient, the extrauterine pregnancy appears to be of the secondary abdominal type.

As alluded to above, the basis for abdominal pregnancy, whether primary or secondary, is only partially understood. At the time of ovulation, the mature ovum is covered with a sticky layer of granulosa cells that must be lysed before fertilization can occur. In some instances, the ovum may remain adherent to the follicle, become fertilized, and implant in the ovary as an ovarian pregnancy. The ovum may float freely in the peritoneal cavity, become fertilized, and gravitate into the cul-de-sac or any location in the peritoneal cavity.[3] Most secondary abdominal pregnancies result from tubal abortion or rupture, with extension and implantation of a viable placenta on the peritoneal surface. The occurrence of the secondary type (incidence of 1/2075 to

1/7931 deliveries) is influenced by previous pelvic infection, surgical adhesions, and tubal occlusion or improper use of antibiotics in pelvic inflammatory disease.[1] Such improper antibiotic use may produce a fibrotic tube, which will permit the passage of the sperm but which will not have a normal lining with peristalsis to permit the passage of the fertilized egg into the uterine cavity.[1,3] Abdominal pregnancy after tubal sterilization has been reported.

The clinical management of abdominal pregnancy is surgical regardless of gestational age or fetal condition, because of the otherwise high risk of placental separation and the incidence of congenital malformations. The maternal mortality rate for abdominal pregnancy is in the range of 4% to 18%.[1] The causes of death include massive hemorrhage caused by manipulating the placenta, sepsis, renal failure, and chronic blood loss. The fetal mortality rate is 90%, with an incidence of fetal deformity ranging from 1% to 100%.

Management of the placenta is variable and is determined by the placenta's location, blood supply, shape, and vascularity. Three different methods for dealing with the placenta are described[1,4]: (1) It can be removed; (2) it can be left in situ and allowed to resorb; (3) methotrexate therapy can be given to hasten resorption. Obviously, the placenta should be removed only when it is safe to do so. Complete removal has been reported in 71% of those patients reaching the third trimester of pregnancy. However, of the three choices available, leaving the placenta untreated or undisturbed now appears to be the most advisable, since the placenta commonly implants on adjacent vital organs and shares blood supply.[4] Under the latter circumstances, surgical removal of the placenta may compromise the blood supply to these organs. The use of methotrexate is limited by its potential for cytotoxic complications. Thus the best course of action, as in our patient, is to ligate the cord close to the placenta and leave it in situ.

Resorption of placental tissue is thought to be a slow process. Ultrasonographic follow-up in our patient showed a decrease in placental size to almost one fourth of its original volume during the first 7 months after delivery. No complication related to the placenta has occurred after 8 months of follow-up.

Preterm birth at 23 to 26 weeks' gestation: Is active obstetric management justified?

Chukwuma G. Nwaesei, M.D., David C. Young, M.D., Joseph M. Byrne, Ph.D., Michael J. Vincer, M.D., Doris Sampson, R.N., Jacquelyn R. Evans, M.D., Alexander C. Allen, M.D., and Dora A. Stinson, M.D.

Halifax, Nova Scotia, Canada

To determine if active perinatal management was justified in preterm deliveries at ≤26 weeks' gestation, the outcome (survival and short- and long-term morbidity) of 43 infants (group I) born between 23 and 26 weeks' gestation was compared with that of 17 infants (group II) born at 27 weeks' gestation. Of the 12 surviving infants in group I (survival 28%), 11 were ventilated (median = 50 days), eight had moderate to severe bronchopulmonary dysplasia, and four had mild retrolental fibroplasia. At follow-up, two infants had physical disabilities with moderate to severe functional impairment, one had a minor disability, and nine had normal neurodevelopment. In contrast, of the 13 surviving infants in group II (survival 76%), nine were ventilated (median = 8 days), six had moderate to severe bronchopulmonary dysplasia, and six had mild RLF. At follow-up, one infant had a physical disability with moderate to severe functional impairment, four had minor disabilities, and eight had normal development. Perinatal factors that positively influenced survival in the two groups combined included active perinatal management, antenatal steroids, female sex, and absence of clinical chorioamnionitis and asphyxia. Although group I infants had a significantly higher mortality rate ($p < 0.05$) and required a longer duration of ventilation ($p < 0.05$), no differences in the incidence of postnatal complications or long-term morbidity at 2 to 4 years of age were evident between the two groups. (Am J Obstet Gynecol 1987;157:890-7.)

Key words: Preterm delivery, active obstetric management, survival, neurodevelopmental outcome

Advances in obstetric and neonatal care and the improvement in survival rates and quality of outcome for very low birth weight infants in recent years have led to a reevaluation in the management of premature deliveries. More specifically, the management of deliveries between 23 and 26 weeks of gestation when the fetus has traditionally been regarded as nonviable, previable, or borderline viable has received increasing attention.[1-5] For perinatologists in tertiary care settings who must deal with these issues regularly and for primary care physicians who must decide whether to transfer such cases to tertiary care centers for further management, the crucial question is, what is the lowest gestational age that justifies active perinatal care? Below what gestational age should there be a hands-off approach by the perinatal team? In other words, how premature is too premature?

From the Department of Neonatal Pediatrics and the Department of Obstetrics and Gynecology, Dalhousie University, the Department of Psychology, IWK Hospital for Children, and the Perinatal Follow-Up Program, Grace Maternity Hospital.

Received for publication July 22, 1986; revised January 21, 1987 and April 21, 1987; accepted May 19, 1987.

Reprint requests: Chukwuma Nwaesei, M.D., Perinatal Follow-Up Program, Grace Maternity Hospital, 5821 University Ave., Halifax, Nova Scotia, Canada B3H 1W3.

At the Grace Maternity Hospital in Halifax, Nova Scotia, Canada (the major high-risk maternal referral center in Nova Scotia with 1000 high-risk deliveries out of 5400 annual deliveries), the approach has been to assume fetal viability and provide active perinatal management for pregnancies terminating at 27 weeks' gestation and above. With deliveries occurring at 26 weeks' gestation or less, there is no clear consensus. Most are treated passively, with regard primarily for maternal considerations.

Such an attitude is supported by previous reports on the outcome of infants born at 26 weeks' gestation or less, which indicate very high mortality rates and uniformly poor long-term neurodevelopment.[6, 7] Because more recent reports have demonstrated an improvement in survival rates and increasing numbers of intact survivors among these extremely preterm infants,[1, 2, 4] it has been suggested that the gestational age limit for active intervention on behalf of the fetus should be lowered even further—from the currently accepted 27 weeks to 24 weeks.[3]

We have reviewed our experience with this group of infants to determine if a change in approach is indicated. We reviewed the outcome of infants born between 23 and 26 weeks' gestation for: (1) survival, (2) short-term morbidity and (3) long-term neurodevel-

opmental status and compared it with that of infants born at 27 weeks' gestation during the same period.

Material and methods

The study population consisted of all liveborn infants delivered between 23 and 27 weeks of gestation within the Grace Maternity Hospital during the 3-year period from Jan. 1, 1980 to Dec. 31, 1982.

Gestational age was based on: (1) firm dates—a first-trimester history with known last normal menstrual period, regular periods, and no birth control pills used in the preceding 6 months and one or both of the following: (2) ultrasound examination in the first trimester with crown rump length agreeing with dates and (3) ultrasound examination between 18 and 20 weeks' gestation with biparietal diameter agreeing with dates, within 6 days.

Inclusion of patients into this study was made exclusively on the basis of assignment of prenatal gestational age. In cases in which there was a discrepancy between prenatal and postnatal assessments, prenatal gestational-age assessment prevailed. One infant with congenital anomalies incompatible with long-term survival has also been excluded from the study. Gestational age was assigned as the last completed week.

The obstetric managment of these patients varied. A key feature in the different approaches was the obstetrician's perception of fetal viability and the decision as to whether cesarean section would be considered evidence of fetal distress in labor or malpresentation (breech). When the fetus was thought to be nonviable by the obstetric staff, a hands-off approach was instituted. Many obstetricians who have made this decision would use no form of fetal monitoring; maternal well-being was the only consideration, with no intervention on behalf of the fetus (passive management). Those obstetricians who considered the fetus viable would attempt to deliver the fetus in the best possible condition, with electronic fetal monitoring used as a guide to timely operative vaginal delivery; others would perform a cesarean section for malpresentation or for fetal distress diagnosed by continuous electronic fetal heart rate monitoring, supplemented by fetal scalp blood pH (active management).

Other management decisions such as the use of tocolytics and/or steroids were largely based on the advancement of labor as indicated by dilatation of the cervix and whether amniotic membranes were ruptured, with gestational age not a crucial factor. Patients were classified as having received steroids if at least 24 hours had elapsed from the first dose to delivery. All obstetric management decisions were carried out under the direct supervision of attending obstetricians.

Neonatal staff attended all deliveries. Resuscitation was with bag and mask and oxygen or more commonly with endotracheal intubation. Each newborn infant was cared for in the special neonatal care nursery under direct supervision of a neonatologist.

Follow-up protocol

An appointment for assessment was offered to all surviving infants at the ages of 2, 3, or 4 years. All were seen at the Perinatal Follow-Up Clinic at the Grace Maternity Hospital, at which time an interim history was obtained and assessment of growth and physical and neurodevelopmental examinations were then carried out. Evidence of hydrocephalus, cerebral palsy, or minor changes in tone was noted. Psychometric assessment was performed by a clinical child psychologist who administered the Bayley Scales of Infant Development to the 2 year olds, and the McCarthy Scales of Children's Abilities to the 3 and 4 year olds, respectively. All scores and physical measurements were corrected for the infant's gestational age. Audiologic assessments were performed by the Nova Scotia Hearing and Speech Clinic, and if the child had not been seen recently by an ophthalmologist, an appointment was offered. None of the medical personnel participating in the follow-up protocol had participated in the perinatal management of these infants.

Definition of terms

Neonatal survival was defined as alive at discharge from the nursery.

Clinical asphyxia was defined as depression at birth that required positive pressure resuscitation for longer than 2 minutes, skin pallor, and abnormal neurologic signs (e.g., marked alteration of muscle tone or seizures).

Clinical chorioamnionitis was defined as malodorous vaginal discharge and/or fever (temperature >37.5° C), with lower abdominal tenderness before delivery. All cases of clinical chorioamnionitis were confirmed by histopathologic evidence of inflammation of the chorionic plate.

Bronchopulmonary dysplasia[8] was defined as follows: (1) respiratory distress beyond 2 weeks of age not otherwise explained and/or P_{CO_2} >60 mm Hg on two or more occasions beyond 1 week of age and (2) chest radiographic changes typical of bronchopulmonary dysplasia.[8]

Retrolental fibroplasia was graded as mild (grades 1 or 2) or moderate to severe (grades 3 and 4).

Physical disability was defined as cerebral palsy and visual or hearing deficits. Cerebral palsy was graded according to motor disabilities. Mild cerebral palsy was defined as a disability in ambulant children that interfered only slightly with normal daily functioning. Such children had hyperreflexia and hypertonicity, and if both lower limbs were affected, a positive Babinski re-

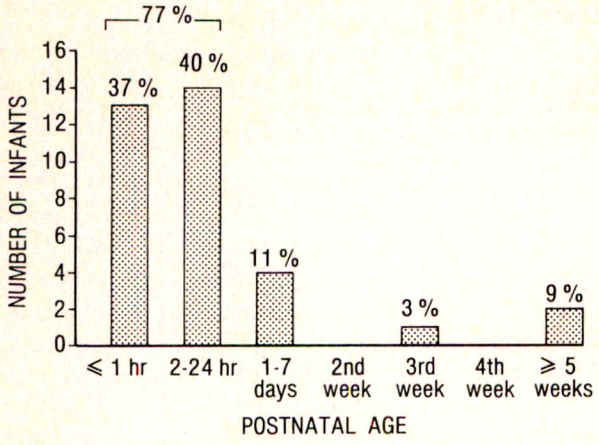

Fig. 1. Age at death.

flex. Moderate cerebral palsy included those children who attempted to walk at 2 years old. Severe cerebral palsy included those children who were likely to remain permanently nonambulant.[9]

Overall neurodevelopmental status was classified as normal or functionally handicap. An infant was considered normal if intellectual potential as measured by either the Bayley Mental Developmental Index or the McCarthy General Cognitive Index was in the normal range (i.e., above 84), and both gross motor and fine motor performances were qualitatively and quantitatively appropriate for the age. Functional handicap was classified according to the degree imposed by single or multiple physical disabilities (severe cerebral palsy, sensory impairment, and cognitive deficits). Severe functional handicap was considered to be present in children who had one or more of the following disabilities: moderate or severe cerebral palsy, a mental developmental index or a general cognitive index <69, and sensorineural deafness that required the use of hearing aids or bilateral blindness. A moderate functional handicap was diagnosed in children with a mental developmental index or a general cognitive index of 69 to 84 and one or more of the following: mild cerebral palsy, sensorineural deafness not requiring amplification, severe myopia, strabismus, or retrolental fibroplasia. Children were classified as having a mild functional handicap if they had either a mental developmental index or a general cognitive index score between 69 and 84 or mild cerebral palsy with a mental developmental index or a general cognitive index score >84.

Statistics

Continuous variables were analyzed by *t* test; discontinuous variables were analyzed by χ^2 test with the Yates correction or Fisher's exact test as needed. p Values <0.05 were considered statistically significant.

Results

Of the 14,776 infants delivered during the study period, 60 met the study criteria. All 60 mothers had a prenatal ultrasound examination in the first trimester and/or between 18 and 20 weeks' gestation. In 17 cases (28%), the crown rump length agreed with maternal dates, and in the remaining 43 cases (72%), the biparietal diameter agreed with the dates within 6 days. The birth weights of the 60 infants ranged from 450 to 1360 gm (mean ± SD = 746 ± 168 gm). Overall survival was 42% (25/60). The mean birth weight (±SD) of the 25 surviving infants was 810 ± 112 gm; for those who died it was 710 ± 187 gm ($p < 0.007$). The number and percentage of surviving infants and the birth weight distribution of the dead and surviving infants at each completed week of gestational age are shown in Table I. As expected, newborn survival at each week of gestation improved with increasing gestational age and was highest for infants at 27 weeks' gestation. The earliest survival was at 24 weeks' gestation (740 gm male). Of the 35 deaths, 13 deaths (37%) occurred within 1 hour of delivery (Fig. 1). An additional 14 infants (40%) died by 24 hours of age. The major causes of death were hyaline membrane disease (8/35, or 23%), extreme immaturity (6/35, or 17%), intrapartum asphyxia (6/35, or 17%), and infection (5/35, or 14%). Of the four infants who died after the first week of age, one infant (930 gm male born at 27 weeks) died at 15 days of age of massive pulmonary hemorrhage after a fulminant course of hyaline membrane disease. Two infants (a 780 gm female infant at 24 weeks and an 800 gm male at 27 weeks) died at 62 days and 168 days of age, respectively, of severe cystic bronchopulmonary dysplasia with pulmonary hypertension. The fourth infant (795 gm male at 25 weeks) died at 76 days of age from overwhelming sepsis, disseminated intravascular coagulopathy, and shock.

Survival

The survival rate in the infants who were 23 to 26 weeks' gestation (group I) was 28% compared with the 76% rate among infants who were 27 weeks' gestation (group II) (Table I). The birth weight and gestational age distribution of study infants in relation to mode of obstetric management is shown in Table II. Only 14 of the 43 infants (33%) in group I were born to mothers who had active obstetric management compared with 15 of 17 infants (88%) in group II. The earliest gestational age at which a cesarean section was performed was 25 weeks. Five patients (12%) received antenatal steroids at least 24 hours before delivery in group I compared with seven patients (41%) in group II. Of the perinatal factors evaluated for their influence on survival in group I infants, only female sex was positively correlated. However, when all study infants

(groups I and II combined) were considered, antenatal steroids, active obstetric management, absence of clinical chorioamnionitis or clinical asphyxia, and female sex were found to be positively correlated with neonatal survival (Table III).

Short-term morbidity

Table IV shows the frequency of postnatal complications in surviving infants born at 23 to 36 weeks and at 27 weeks' gestation. Major postnatal complications among surviving infants were bronchopulmonary dysplasia and retrolental fibroplasia.

Group I (infants 23 to 26 weeks' gestation). Of the 12 surviving infants born between 23 and 26 weeks' gestation, seven had idiopathic respiratory distress syndrome and required ventilatory support. Four additional infants in this group who had severe recurrent apnea also required ventilatory assistance. Not all infants were evaluated for intracranial hemorrhage by real-time ultrasonography, since this technique was not used routinely in our nursery until 1981. Of the nine infants in this group who had serial cranial ultrasound evaluation, five had no hemorrhage, two had hemorrhage into the germinal matrix, one had intraventricular hemorrhage with arrested ventriculomegaly, and one infant had bilateral intraparenchymal hemorrhage with hydrocephalus requiring ventriculoperitoneal shunt. Eight infants had moderate to severe bronchopulmonary dysplasia that required prolonged ventilation. Of the five infants in this group with patent ductus arteriosus, three required surgical ligation. All four infants with retrolental fibroplasia had only mild disease (grades 1 and 2).

Group II (infants 27 weeks' gestation). Of the 13 surviving infants born at 27 weeks' gestation, nine developed respiratory distress syndrome and required ventilatory support. Of the nine infants screened for intraventricular hemorrhage, only one infant had evidence of hemorrhage (germinal matrix hemorrhage only). Eight infants in this group had varying degrees of bronchopulmonary dysplasia, and all six infants with retrolental fibroplasia had only mild forms of the disease. Five of the nine infants with patent ductus arteriosus required surgical ligation of the duct.

There was no difference in the mean duration of hospital stay among the two groups of gestational-age infants.

Long-term follow-up (groups I and II)

All surviving infants were between 2 and 4 years of age at the time of developmental evaluation. Of the 12 survivors, in group I, six were two years old, five were 3 years old, and one was 4 years old, respectively, at the time of assessment. Of the 13 survivors in

group II, seven were two years old, three were 3 years old, and three were 4 years old. Table V compares the long-term neurodevelopmental outcome in the two groups of infants. There was no statistically significant difference in the incidence of functional handicap or physical disabilities among the two groups of surviving infants. Two of 12 (17%) surviving infants in group I and one of 13 (7%) surviving infants in group II had physical disabilities.

The nature and severity of physical and functional handicap of affected infants are shown in Table VI.

Comment

For many decades, birth weight has been used as a convenient characteristic against which to measure survival prospects of premature infants. It was readily available, objective, and served to circumvent the difficulties of accurate determination of gestational age because of the uncertainties of the last normal menstrual period. Survival statistics based on birth weights largely served the interest of the neonatologist and had limited value to the obstetrician who must make the critical management decision before delivery. Although

birth weight and gestational age have been shown to be major determinants of neonatal survival,[10] gestational age better reflects fetal maturation and is therefore more likely to be a better predictor of outcome. In a study of the survival of infants born at 24 to 28 weeks' gestation that used multivariate analysis, Herschel et al.[2] showed that gestational age made the most significant contribution to outcome; birth weight did not add to the discrimination. More recently, in a cohort of 1338 very premature and/or very low birth weight infants representing 94% of all liveborn infants at 32 weeks' gestation or less, Verloove-Vanhorick et al.[10] found that gestational age was a better predictor of neonatal survival than was birth weight. Therefore future studies on preterm infants are encouraged to place greater emphasis on gestational age, and not postnatal birth weight as the crucial independent variable affecting neonatal survival. Our neonatal survival rate at each completed week of gestation is comparable with that reported by others.[2, 6]

The survival of preterm infants partly depends on whether the obstetrician believes that the fetus is viable.[11, 12] Our aim was to determine if the nature of obstetric management (active or passive) at 23 to 26 weeks' gestation influenced neonatal survival. This was a difficult task, since the obstetrician's attitude does not readily lend itself to experimental investigation. Our definition of active obstetric management included all cases of assumed fetal viability in which the ultimate goal of management was to avoid fetal hypoxia and acidosis. This did not necessarily imply cesarean section. Other management maneuvers considered equally important included careful positioning of mother, generous use of oxygen in cases of suspected fetal distress, and avoidance of depressant drugs as much as possible during labor. In our institution during the review period, no delivery occurring earlier than 24 weeks was actively managed. Of the 14 deliveries between 24 and 26 weeks' gestation that had active obstetric management, seven infants (50%) survived. In contrast, only five of 22 infants (23%) born at 24 to 26 weeks' gestation whose mothers had not been actively managed in labor survived. Although this difference did not achieve statistical significance, there certainly was a trend for infants delivered to mothers who had been actively managed in labor to do better. However, when infants born at 27 weeks' gestation were included in the analysis, active intervention was clearly beneficial. Because many more infants were actively managed at 27 weeks' gestation (15/17, or 88%) than at ≤26 weeks (14/43, or 32%), the apparent difference observed in the analysis of the whole group may very well reflect the influence of gestational age and the mode of obstetric management.

Because very few mothers (5/43) received steroids at 26 weeks' gestation or less, the possible influence of this

management decision on neonatal survival at these gestations is difficult to determine.

The optimal mode of delivery for malpresentation in preterm infants remains controversial. Although some reports strongly favor the abdominal route,[1, 12] others are unable to show any impact of delivery method on neonatal survival.[13, 14] In a recent review of the impact of cesarean birth on preterm breech presentation, Bodmer et al.[15] concluded that although cesarean section was performed least often among extremely premature infants (25 to 28 weeks' gestation), these cases may prove most beneficial. During the period of our review, of 15 infants who were in breech presentations or with transverse lie at ≤26 weeks' gestation, only two (13%) were delivered by cesarean section. In contrast, two of four infants (50%) with malpresentation at 27 weeks' gestation were delivered by cesarean section. Because delivery by cesarean section for malpresentation was used more frequently when the infant was more mature, the improved survival advantage may only reflect gestational maturation. The advantage that was due to the method of delivery was unclear. Thus no conclusions can be drawn about abdominal delivery of infants at ≤26 weeks' gestation from this report because the numbers were too small.

It has recently been suggested that occult antepartum infection of the genital tract could be an important cause of preterm delivery.[16] Our data show a negative impact of clinical chorioamnionitis on neonatal survival for the whole group. The trend is similar for the infants born at ≤26 weeks' gestation but is not statistically significant (Table III).

Except for differences in the duration of ventilation, we were unable to demonstrate any other significant differences in postnatal morbidity (Table IV) between surviving infants born at ≤26 weeks' gestation and those born at 27 weeks. In this regard, our results contrast with those of Gilstrap et al.,[13] who reported significantly more serious postnatal morbidity among surviving infants born between 23 and 26 weeks' gestational age.

Earlier reports of long-term neurodevelopmental status of extremely premature infants showed uniformly poor outcome.[6, 7] Bennett-Britton et al.[6] reviewed the outcome of 158 infants weighing ≤800 gm at birth in a referral neonatal intensive care unit and found no intact survivors with gestational age ≤26 weeks or birth weight ≤700 gm. Our study population differs from that of Bennett-Britton et al.[6] in that it was inborn but is similar to that of Yu et al.,[4] who have recently reported more encouraging findings in gestational age groups identical to ours. Of 35 survivors born between 24 and 26 weeks' gestation, these investigators reported a 74% satisfactory outcome at 2 years of age. The present report has the advantage of a much longer period of follow-up and represents a 100% follow-up, with every survivor undergoing developmental assessment (Table V).

In summary, we have reviewed the outcome of infants born between 23 and 26 weeks' gestation (group I) in comparison with infants born at 27 weeks' gestation (group II). Group I infants had a significantly higher mortality rate, most notably at 23 and 24 weeks' gestation, and required a longer duration of ventilatory support. No other differences were evident between the two groups.

Analysis of perinatal factors showed that for groups I and II combined, active obstetric management, antenatal steroids, and female sex were associated with increased survival, whereas the presence of clinical chorioamnionitis and asphyxia resulted in increased death. When infants born at ≤26 weeks' gestation (group I) were analyzed separately, there was a trend for infants whose mothers had been actively managed in labor to have a better outcome, but this trend did not reach statistical significance.

It could be argued that intensive perinatal care should be widely extended to all deliveries occurring between 23 and 26 weeks' gestation, with the expectation that sooner or later perinatologists would become sufficiently adept to allow even the youngest infant to survive without major impairment. A prospective study designed with such an approach would have greater validity in addressing the gestational-age threshold question. However, the ethical, psychological, and economic implications of such an approach must also be addressed. Our data suggest a favorable long-term outcome for surviving infants born between 24 and 26 weeks' gestation but does not answer the question whether active perinatal management of these deliveries should become a standard practice. Further study is required to address this question.

The high neonatal loss among deliveries occurring between 23 and 26 weeks' gestations dictates that efforts aimed primarily at postponing deliveries beyond 26 weeks, or better still, eliminating premature delivery, should remain the mainstay of therapy. Until this is achievable, obstetric management decisions involving these deliveries will have to be made on an individual basis, keeping in mind that very preterm infants can have a favorable long-term outcome.

Inhibitory effect of quinidine on plasma pseudocholinesterase activity in pregnant women

J. Reddy Kambam, M.D., John J. Franks, M.D., and Bradley E. Smith, M.D.
Nashville, Tennessee

The effect of quinidine at therapeutic and subtherapeutic concentrations on pseudocholinesterase activity in the plasma of 16 normal pregnant women was studied. The mean plasma pseudocholinesterase activity in the absence of quinidine (control) was 0.67 ± 0.11 U/ml. The mean pseudocholinesterase activity in the presence of quinidine at concentrations of 0.5, 1.0, 2.0, and 5.0 μg/ml was 0.48 ± 0.09, 0.38 ± 0.09, 0.29 ± 0.10, and 0.19 ± 0.09 U/ml, respectively. At therapeutic concentrations needed to treat cardiac arrhythmias (2 to 5 μg/ml), quinidine inhibited pseudocholinesterase activity by 60% to 70%. All the plasma samples had a normal dibucaine number (78 to 85). We recommend caution when succinylcholine and/or ester-type local anesthetics are used in pregnant women receiving quinidine. (AM J OBSTET GYNECOL 1987;157:897-9.)

Key words: Pregnancy, quinidine sulfate, plasma pseudocholinesterase

Pregnancy is associated with a significant decrease in plasma pseudocholinesterase activity.[1, 2] Pseudocholinesterase is responsible for the rapid metabolism of succinylcholine, a depolarizing muscle relaxant. Succinylcholine is still the most popular muscle relaxant used for rapid sequence intubation of the trachea in pregnant patients. Pseudocholinesterase is also responsible for hydrolysis of ester-type local anesthetics including procaine, tetracaine, cocaine, and chloroprocaine. Several pharmacologic agents interfere with the metabolism of these ester-type drugs by depressing pseudocholinesterase activity.[3-5] Quinidine, a potent antiarrhythmic agent, is known to prolong the muscle paralysis caused by succinylcholine.[6] The mechanism for prolongation of action of succinylcholine caused by quinidine is not well understood. Furthermore, the effect of quinidine at therapeutic concentrations (2 to 5 μg/ml) on pseudocholinesterase activity in pregnant women has not been reported. Recently we observed two cases of prolongation of succinylcholine duration of action in patients receiving quinidine. We also documented desensitization block after succinylcholine administration in a patient receiving quinidine sulfate. When measured after surgery pseudocholinesterase ac-

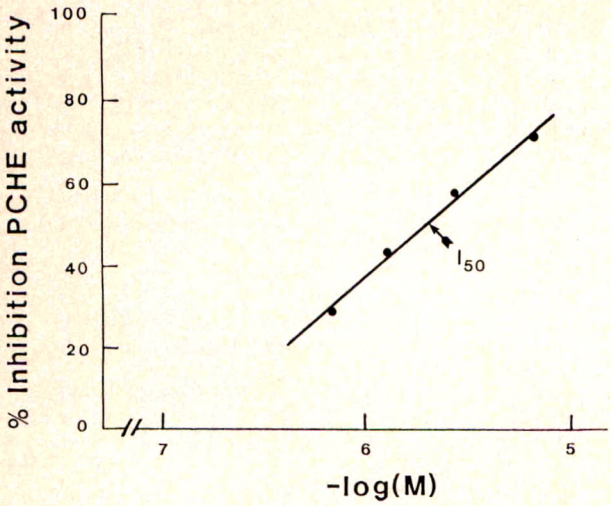

Fig. 1. Inhibitory effect of quinidine on plasma pseudocholinesterase activity. (I_{50} = 1.50 μg/ml; *PCHE* = pseudocholinesterase.)

tivity was significantly reduced in these patients. Therefore we studied the effect of quinidine on pseudocholinesterase activity in the plasma of 16 normal pregnant women.

Methods

With prior approval from our institutional review board for the protection of human subjects, we included 16 normal pregnant women (ages 18 to 35 years) in our study. Five milliliters of venous blood was withdrawn into a heparinized syringe from each women. Plasma was immediately separated and used for the determination of pseudocholinesterase activity and dibucaine numbers. A kinetic method described by Zapf and Coghlan[7] was used for the determination of pseudocholinesterase activity and dibucaine numbers. The effect of quinidine at concentrations of 0.5, 1.0, 2.0, and 5.0 μg/ml was also studied on pseudocholinesterase activity in each sample of plasma. Pseudocholinesterase activity was expressed as units per milliliter of plasma. One unit corresponds to the liberation of 1 μmol of 1-naphthol/min under the conditions of enzyme assay.

A randomized block analysis of variance within treatment levels and testing by the Dunnett test were used to compare the drug effects against the control. A difference was considered significant if $p < 0.05$.

Results

Table I contains the results of all the plasma samples. The mean pseudocholinesterase activity (control) of the pregnant women was 0.67 ± 0.11 U/ml. Pseudocholinesterase activity in the presence of quinidine at concentrations of 0.5, 1.0, 2.0, and 5.0 μg/ml was 0.48 ± 0.09, 0.38 ± 0.09, 0.29 ± 0.1, and 0.19 ± 0.09 U/ml, respectively. There was 29%, 43%, 57%, and 71% depression of pseudocholinesterase activity in the presence of quinidine at concentrations of 0.5, 1.0, 2.0, and 5.0 μg/ml, respectively. Dibucaine numbers of all the samples were in the normal range of 78 to 85.

Table I. Effect of quinidine on plasma pseudocholinesterase activity in pregnant women n = 16

Quinidine (μg/ml)	*Plasma pseudocholinesterase activity* (U/ml) (mean ± SD)*	*% inhibition of plasma pseudocholinesterase*
0 (control)	0.67 ± 0.10	—
0.5	0.48 ± 0.09	29
1.0	0.38 ± 0.09	43
2.0	0.29 ± 0.10	57
5.0	0.19 ± 0.09	71

*Significance of difference when compared with control; $p < 0.01$ (Dunnetts test).

Our results show a significant inhibitory effect of quinidine on pseudocholinesterase activity within treatment levels ($p < 0.001$). A Dunnett test clearly demonstrated a statistical difference in all treatment levels from the control ($p < 0.01$).

Fig. 1 shows a plot of percentage pseudocholinesterase inhibition against plasma quinidine concentrations. Linear correlation is evident as indicated by a correlation coefficient (R) of 0.99. Fig. 1 also shows that the plasma quinidine concentration required to inhibit 50% of the pseudocholinesterase activity was 1.50 μg/ml.

Comment

Pseudocholinesterase is a mucoprotein synthesized mainly in the liver. Both normal and preeclamptic pregnancies are associated with a significant decrease in pseudocholinesterase activity.[1, 2] The mechanisms for decreased pseudocholinesterase activity in pregnancy have not been elucidated.

Quinidine, a potent antiarrhythmic drug, is used to treat both atrial and ventricular arrhythmias. Quinidine is preferred to procainamide in the long-term management of arrhythmias because administration of procainamide is associated with drug-induced lupus erythematosus.

Our present data show that there is a significant decrease in pseudocholinesterase activity in normal pregnancy (0.67 U/ml) when compared with our normal mean value of normal nonpregnant women (0.9 U/ml). Our data also show that quinidine at concentrations needed to treat arrhythmias (2 to 5 μg/ml) depressed pseudocholinesterase activity an additional 60% to 70% from the control value of normal pregnancy.

We believe that it is important to be aware of this quinidine effect on pseudocholinesterase activity since systemic toxicity can occur after the epidural admin-

istration of ester-type local anesthetics. Systemic central nervous system toxicity after the administration of 2-chloroprocaine by means of an epidural has been documented in a young pregnant patient who apparently had less than 50% of normal level of pseudocholinesterase activity.[8] Moreover, because of the extremely low levels of pseudocholinesterase activity associated with therapeutic levels of quinidine, pregnant women should be monitored with a nerve stimulator for both the duration of action of succinylcholine and for desensitization block that may result after the administration of succinylcholine.

In conclusion, our data show that quinidine has a significant inhibitory effect on pseudocholinesterase activity in the plasma of pregnant women. Quinidine at therapeutic concentrations of 2 to 5 μg/ml depressed pseudocholinesterase activity by 60% to 70%. We recommend caution when succinylcholine and/or ester-type local anesthetics are administered to pregnant women who also receive quinidine.

Umbilical artery flow velocity waveforms and the placental vascular bed

Lesley M. McCowan, M.B., Brendan M. Mullen, M.D., and Knox Ritchie, M.D.
Toronto, Ontario, Canada

Umbilical artery Doppler studies were performed close to delivery in 17 women (seven with healthy pregnancies and 10 complicated by intrauterine growth retardation), and results were analyzed by calculating the pulsatility index. In each case the placenta was examined histologically, and the small arteries and arterioles were counted in the tertiary stem villi. A highly significant negative linear relationship was found between pulsatility index and mean small arterial vessel count per field ($r = 0.71$, $p < 0.01$). This suggests that when the pulsatility index is raised (indicating increased resistance), one possible explanation may be obliteration of small placental arteries. (Am J Obstet Gynecol 1987;157:900-2.)

Key words: Umbilical artery, Doppler, flow velocity waveforms, placenta

Quantification of flow velocity waveforms of the umbilical artery obtained with Doppler ultrasound examination has become recognized as a potentially useful additional method of fetal assessment.[1] In adult vascular studies, end-diastolic velocity has been related to peripheral resistance.[2] Accordingly, a variety of distinct waveforms have been described in deep abdominal and pelvic arteries, with the characteristic of each dependent on the individual vascular bed.[3] In normal pregnancy there is a progressive increase in end-diastolic velocity[4] and hence a steady fall in peripheral resistance in the umbilical-placental circulation. Reduced, absent, or even reversed end-diastolic flow velocity may occur in pregnancies complicated by severe intrauterine growth retardation,[4] and such waveforms are associated with an increased risk of perinatal death[4] and low Apgar scores.[5]

Various hypotheses have been proposed to explain these changes, such as an increase in fetal whole-blood viscosity.[4] In a recent study Giles et al.[6] have demonstrated reduced mean small arterial vessel counts in placentas from pregnancies with abnormal flow velocity waveforms of the umbilical artery. They proposed that an increase in placental bed resistance caused by obliteration of these small vessels is the primary cause of the change observed in the flow velocity waveforms of the umbilical artery.

Other investigators have not noted consistent morphologic changes in placentas from growth-retarded pregnancies.[7] This study was undertaken in an attempt to resolve some of this controversy. Changes in flow velocity waveforms were compared with the mean small arterial vessel count in the placenta from both normal pregnancies and those complicated by intrauterine growth retardation.

Patients and methods

Umbilical artery Doppler studies were performed in 17 pregnancies. Seven women were healthy with uncomplicated pregnancies and were delivered of babies who were appropriate for gestational age. All these women were studied within 3 days of birth. The other 10 women had pregnancies complicated by severe intrauterine growth retardation of varying etiology, and all were studied on the day of delivery. All birth weights were less than two standard deviations below the mean.[8] By studying the two diverse groups, it was hoped that a wide range of flow velocity waveforms of the umbilical artery would be obtained for analysis. A continuous-wave Doppler instrument (Bach-Simpson, London, Ontario, Canada) with a 4 MHz probe and a power output of 80 mW/cm^2 at the transducer surface was used in every case. The Doppler-shifted frequencies were processed by a spectral analyzer (Advanced Technology Laboratories, Bothwell, Wash.), and when the best auditory and visual signals were obtained, a hard copy printout was taken to include 10 waveforms, which were subsequently analyzed by calculating the pulsatility index as shown in Fig. 1.

The pulsatility index was selected as the optimal method of analysis, since a gradation of results can be obtained even when end-diastolic velocity is absent or

reversed whereas the systolic to diastolic ratio becomes infinity or negative, respectively. The pulsatility index results were not known by the pathologist examining the placental material.

Each placenta was studied by a modification of the method of Giles et al.[6] Immediately after delivery the umbilical cord was clamped, the placenta was weighed and measured, and then fixed in 10% neutral-buffered formalin for 3 to 4 days. The placenta was then cut longitudinally at 1.5 cm intervals, and five blocks of each placenta were selected at random for study. Samples taken from areas of infarction or within zones less than 2 cm from the cord insertion or the placental margin were excluded. The 2 cm zone beneath the cord insertion was excluded because of the finding by Giles et al.[6] that samples selected from this region were significantly different from other regions. Samples from the placental margin were excluded because of the high prevalence of intervillous fibrin deposition. The tissues were processed for histologic examination in the usual manner, cut at 5 μm thickness, and stained with hematoxylin-eosin and Gomori trichrome one-step stain.

The histologic analysis was performed with a camera lucida and an International Business Machine personal computer computer-assisted digitizing board. Five fields (× 100 magnification, 1.8 mm diameter) from the midzone of each section were studied (25 fields/placenta). Areas of placental infarction, intervillous fibrin deposition, and primary stem and anchoring villi were excluded. We counted the number of arteries, arterioles, and tertiary stem villi in each field. All results were expressed as the mean value per field for each placenta.

Regression analysis was performed, and the correlation coefficient, p value, and r square values were determined.

The mean gestational age of the intrauterine growth retardation group was 31 weeks ± 3 days while that of the control group was 37 weeks ± 5 days. The mean birth weight in the intrauterine growth retardation group was 1053 ± 459 gm and 3054 ± 1245 gm in the control group.

Results

The mean small arterial vessel count was determined in all cases, and a highly statistically significant linear association was found between increasing pulsatility index and reduced mean arterial count ($r = 0.71$ $p < 0.01$). The results are demonstrated in Fig. 2. The r square value was 0.50, which indicates that 50% of the variation seen in the pulsatility index may be explained by mean small arterial vessel count. As might be expected, the highest pulsatility index values and lowest mean small arterial vessel counts in the placenta

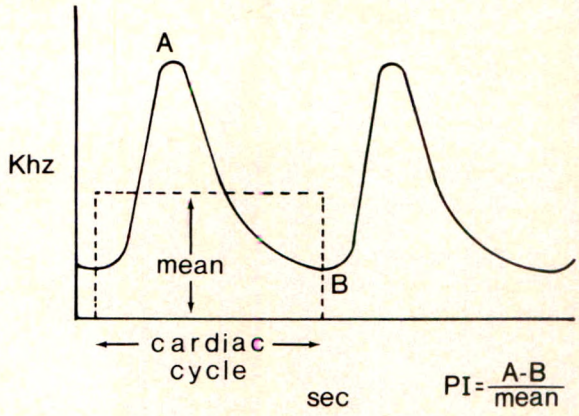

Fig. 1. Schematic flow velocity waveform indicating the method for calculating the pulsatility index *(PI)*.

were obtained when the fetus was growth retarded, whereas in normal pregnancies the pulsatility index values were low and mean small arterial vessel counts were high.

A modal count of the small arterial vessels was also determined in all cases so that a comparison could be made between our results and those of Giles et al.[6] This comparison could not be completed because eight of the 19 cases studied had more than one modal value.

A strong negative correlation was found in this study between the pulsatility index and mean small arterial vessel count, thus when the pulsatility index is elevated (indicating increased peripheral resistance), mean small arterial vessel count is also reduced. This suggests that the abnormal flow velocity waveforms of the umbilical artery may be at least partly explained by the reduced numbers of these vessels, which are the prime regulators of peripheral resistance.[9]

There was no difference in tertiary stem villous count between patients with normal and abnormal pulsatility index values and hence the reduced mean small arterial vessel count seen in some cases cannot be explained on the basis of a reduced number of tertiary stem villi.

The results of this study confirm the findings of Giles et al.[6] who initially reported reduced numbers of small placental arterial vessels in women with abnormal umbilical flow velocity waveforms. From our study it was not possible to say whether the reduced number of vessels was because of failure of development or obliteration. Giles et al.[6] observed collections of nuclear material in some abnormal placentas, which they felt may have represented obliteration of a small artery. An obliterative process would be supported by the fact that in some pregnancies flow velocity waveforms of the umbilical artery may be normal initially and become progressively abnormal with advancing gestation.

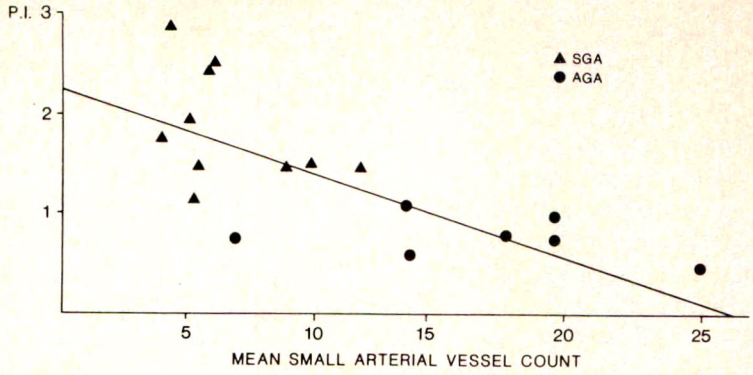

Fig. 2. Correlation between pulsatility index and mean small arterial vessel count ($r = 0.71, p < 0.01$). (*SGA* = Small for gestational age; *AGA* = appropriate for gestational age.)

The mechanism leading to this suspected obliteration is not known. However, the most likely hypothesis suggested by Rankin and McLaughlin[10] is that reduced uteroplacental perfusion results in uteroplacental ischemia, which leads to placental vasoconstriction. If this process was prolonged or severe, obliteration of the vessels could occur.

In summary, a highly significant linear correlation was found between flow velocity waveforms of the umbilical artery quantified by the pulsatility index and the mean placental small arterial vessel count. This suggests that when the pulsatility index is raised (indicating increased resistance), the major cause is obliteration of small placental arteries.

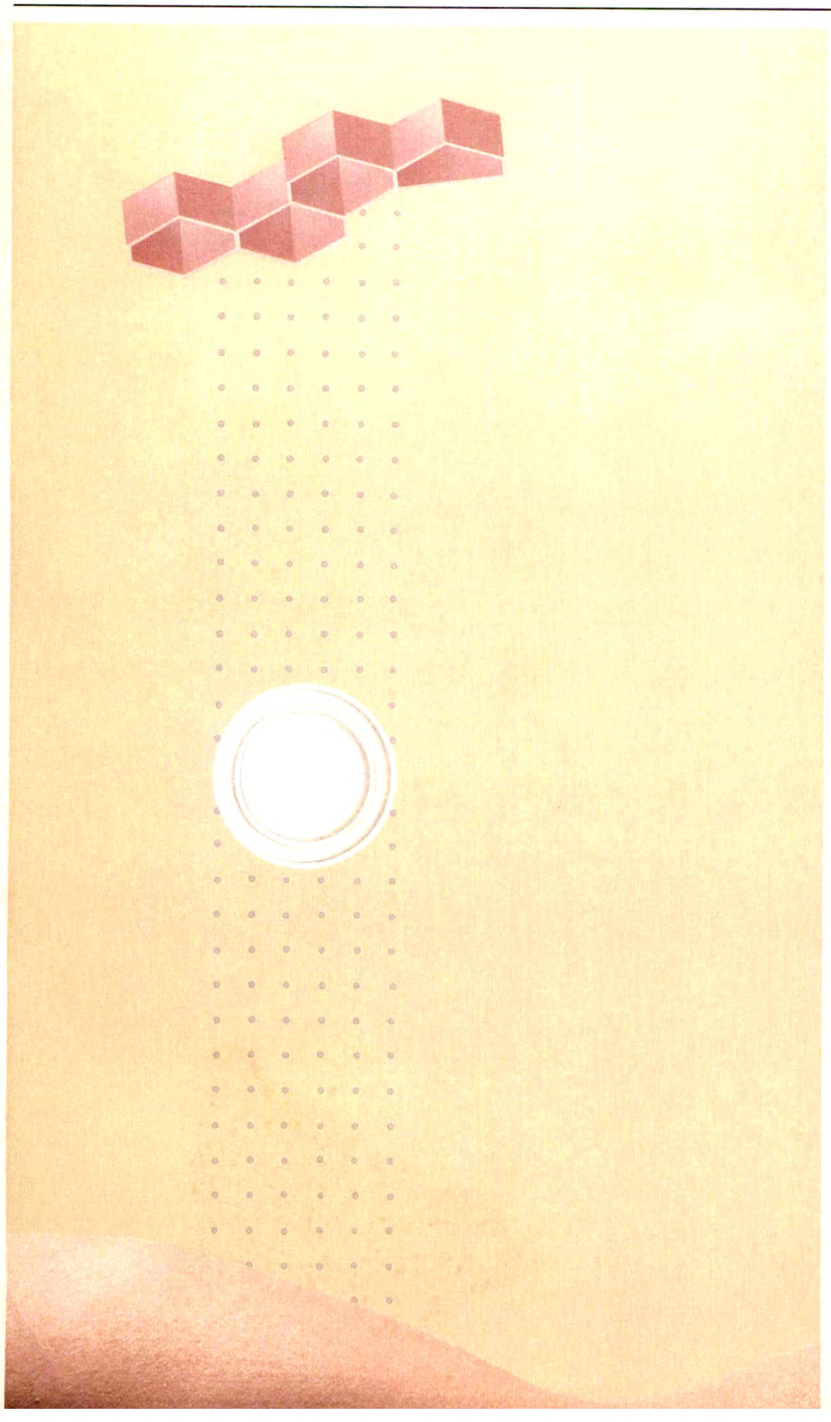
Now

The next generation of estrogen replacement therapy...



transdermal delivery

ESTRADERM®

estradiol transdermal syste

Combines the advantages of transdermal delivery...

A specially designed transdermal delivery system

Providing the natural ovarian estrog (17-beta estradiol) directly to the bloodstream and target organs; with no first-pass liver metabolism, perm use of extremely low dosage

Effectively controls estrogen deficiency symptoms

Steady-state relief of hot flashes, oth menopausal symptoms associated w hot flashes, and vaginal discomfort

Well tolerated

Very low incidence of systemic side effects...few local problems of consequence

Easy to use; transdermal delivery preferred 3:1 by patients over tablets[1]

Usual starting dose: a 0.05-mg syste changed twice weekly

BRIEF SUMMARY OF PRESCRIBING INFORMATION.
PLEASE SEE FULL PRESCRIBING INFORMATION.

ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than 1 year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer-reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.

The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5-13.9 times greater than in nonusers. The risk appears to depend both on duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen.

Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy.

There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that women who had been exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than four per 1000 exposures. Furthermore, a high percentage of such exposed women (30-90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data on the use of other estrogens are not available, it cannot be presumed they would not induce similar changes.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case control study estimated a 4.7-fold increased risk of limb-reduction defects in infants who had been exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one per 1000.

In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses.

If Estraderm is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and of the advisability of continuation of the pregnancy.

INDICATIONS AND USAGE

Estraderm is indicated for the treatment of the following: moderate-to-severe vasomotor symptoms associated with menopause; female hypogonadism; female castration; primary ovarian failure; and atrophic conditions caused by deficient endogenous estrogen production, such as atrophic vaginitis and kraurosis vulvae.

Studies of the addition of a progestin for seven or more days of a cycle of estrogen administration have reported a lowered incidence of endometrial hyperplasia. Morphological and biochemical studies of endometrium suggest that 12 to 13 days of progestin are needed to provide maximal maturation of the endometrium and to eliminate any hyperplastic changes. Whether this will provide protection from endometrial carcinoma has not been clearly established. There are possible additional risks that may be associated with the inclusion of progestin in estrogen replacement regimens. The potential risks include adverse effects on carbohydrate and lipid metabolism. The choice of progestin and dosage may be important in minimizing these adverse effects.

CONTRAINDICATIONS

Estrogens should not be used in women or men with any of the following conditions:

1. known or suspected cancer of the breast;
2. known or suspected estrogen-dependent neoplasia;
3. known or suspected pregnancy (see Boxed Warning);
4. undiagnosed abnormal genital bleeding;
5. active thrombophlebitis or thromboembolic disorders;
6. history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use.

WARNINGS

1. Induction of Malignant Neoplasms. Long-term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. There are now reports that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning.)

At the present time, there is no satisfactory evidence that estrogens given to postmenopausal women increase the risk of breast cancer, although a recent long-term follow-up of a single physician's practice has raised this possibility. Because of the animal data, there is a need for caution in prescribing estrogens for women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms.

2. Gallbladder Disease. A recent study has reported a two- to threefold increase in the risk of surgically confirmed gallbladder disease in postmenopausal women receiving oral estrogens, similar to the twofold increase previously noted in users of oral contraceptives.

3. Effects Similar to Those Caused by Estrogen-Progestogen Oral Contraceptives. There are several serious adverse effects of oral contraceptives and other high-dose oral estrogen treatments, most of which have not, up to now, been documented as consequences of postmenopausal estrogen replacement therapy. This may reflect the comparatively low doses of estrogen used in postmenopausal women.

a. Thromboembolic Disease. It is now well established that users of oral contraceptives have an increased risk of various thromboembolic and thrombotic vascular diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. There is evidence that the risk of several of these adverse reactions is related to the dose of the drug. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least four weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization.

While an increased rate of thromboembolic and thrombotic disease in postmenopausal users of estrogens has not been found, this does not rule out the possibility that such an increase may be present or that subgroups of women who have underlying risk factors or who are receiving relatively large doses of estrogens may have increased risk. Therefore, estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders, and they should not be used in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed.

Large doses of estrogen (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown in a large prospective clinical trial in men to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis. When estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptive use should be considered a clear risk.

b. Hepatic Adenoma. Benign hepatic adenomas have been associated with the use of oral contraceptives. Although benign and rare, these tumors may rupture and cause death from intra-abdominal hemorrhage. Such lesions have not yet been reported in association with other estrogen or progestogen preparations, but they should be considered if abdominal pain and tenderness, abdominal mass, or hypovolemic shock occurs in patients receiving estrogen. Hepatocellular carcinoma has also been reported in women taking estrogen-containing oral contraceptives. The causal relationship of this malignancy to these drugs is not known.

c. Elevated Blood Pressure. Women using oral contraceptives sometimes experience increased blood pressure which, in most cases, returns to normal upon discontinuing the drug. There is now a report that this may occur with use of oral estrogens in the menopause and blood pressure should be monitored with estrogen use, especially if high doses are used. Ethinyl estradiol and conjugated estrogens have been shown to increase renin substrate. In contrast to these oral estrogens, transdermally administered estradiol does not affect renin substrate.

d. Glucose Tolerance. A worsening of glucose tolerance has been observed in a significant percentage of patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed while receiving estrogen.

4. Hypercalcemia. Administration of high doses of estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases. If hypercalcemia occurs, use of the drug should be stopped and appropriate measures should be taken to reduce the serum calcium level.

PRECAUTIONS

General

1. A complete medical and family history should be taken before initiation of any estrogen therapy. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, as well as a cervical Papanicolaou test. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed.
2. Because estrogens may cause some degree of fluid retention, careful observation is required when conditions that might be influenced by this factor are present (e.g., asthma, epilepsy, migraine, and cardiac or renal dysfunction).
3. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as uterine bleeding, mastodynia, etc.
4. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Estrogens should be used with caution in patients who have or have had endometriosis.
5. Oral contraceptives appear to be associated with an increased incidence of mental depression. Although it is not clear whether this is due to the estrogenic or progestogenic component of the contraceptive, patients with a history of depression should be carefully observed.
6. Preexisting uterine leiomyomata may increase in size during prolonged estrogen use. If this occurs, estrogen therapy should be discontinued while the cause is investigated.
7. In patients with a history of jaundice during pregnancy, there is an increased risk that jaundice will recur with the use of estrogen-containing oral contraceptives. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated.
8. Estrogens may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients.
9. Because the prolonged use of estrogens influences the metabolism of calcium and phosphorus, estrogens should be used with caution in patients with metabolic bone diseases associated with hypercalcemia and in patients with renal insufficiency.

Drug/Laboratory Test Interactions

The results of certain endocrine and liver function tests may be affected by estrogen-containing oral contraceptives. The following changes have been observed with large doses of oral estrogen:

1. increased sulfobromophthalein retention;
2. increased prothrombin time; increased factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability;
3. increased thyroxine-binding globulin (TBG), leading to increased circulating total thyroid hormone (T_4) as measured by column or radioimmunoassay; free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered; TBG was not affected in clinical trials of Estraderm;
4. reduced response to the metyrapone test;
5. reduced serum folate concentration;
6. increased serum triglyceride and phospholipid concentration, and decreased pregnanediol excretion.

The pathologist should be informed that the patient is receiving estrogen therapy when relevant specimens are submitted.

Carcinogenesis, Mutagenesis, Impairment of Fertility

See **WARNINGS** and Boxed Warning.

Long-term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

Pregnancy Category X

See **CONTRAINDICATIONS** and Boxed Warning.

Estrogens should not be used during pregnancy.

Nursing Mothers

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS

See **WARNINGS** and Boxed Warning regarding potential adverse effects on the fetus, induction of malignant neoplasms, increased incidence of gallbladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.

The most commonly reported adverse reaction to Estraderm in clinical trials was redness and irritation at the application site. This occurred in about 17% of the women treated and caused approximately 2% to discontinue therapy. Reports of rash have been rare.

The following additional adverse reactions have been reported with estrogenic therapy, including oral contraceptives:

Genitourinary System: Breakthrough bleeding, spotting, change in menstrual flow; increase in size of uterine fibromyomata; change in cervical erosion and amount of cervical secretion.

Endocrine: Breast tenderness, breast enlargement.

Gastrointestinal: Nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice have been observed with oral estrogen therapy.

Eyes: Steepening of corneal curvature; intolerance to contact lenses.

Central Nervous System: Headache, migraine, dizziness.

Miscellaneous: Change in weight, edema, change in libido.

Do not store above 86°F (30°C).

Do not store unpouched. Apply immediately upon removal from the protective pouch.

CAUTION: Federal law prohibits dispensing without prescription.

Maternal-Fetal Medicine

Board certified/eligible PERINATOLOGISTS required for large volume obstetric services (3,000-6,000 deliveries per year).

Opportunities exist both to join and to create high risk obstetric services. The Southern California Permanente Medical Group has some openings for exclusive perinatal practice. However, not all areas have the volume of high risk patients to offer such exclusive practice. Perinatologists who wish to perform other aspects of obstetric and gynecologic practice may do so. University affiliations and clinical research is encouraged.

Salaries are competitive and the benefits offered are outstanding. They include: professional liability, medical and dental coverage, vacation and sick leave, continuing education, life insurance and retirement plans. After two years full time employment, physicians are eligible for consideration to the partnership.

TRI·LEVLEN™ 28
TRI·LEVLEN™ 21

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

BRIEF SUMMARY

Tri-Levlen™—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information and package insert.

Adenosquamous carcinoma of the fallopian tube

A clinicopathologic case report with verification of the diagnosis by immunohistochemical and ultrastructural studies

David H. Moore, M.D., John T. Woosley, M.D., Ph.D., Robert L. Reddick, M.D., M.S., Leslie A. Walton, M.D., and Gene P. Siegal, M.D., Ph.D.

Chapel Hill, North Carolina

A middle-aged woman presented with a pelvic mass. Pathologic examination of the resected specimen revealed a primary adenosquamous carcinoma of the left fallopian tube. Special studies supported the concept of the neoplastic cells differentiating along two major pathways, squamous cell carcinoma and mucin-producing adenocarcinoma. (Am J Obstet Gynecol 1987;157:903-5.)

Key words: Fallopian tube neoplasia, adenosquamous carcinoma, keratin immunohistochemistry, electron microscopy

Fallopian tube cancer is the rarest of gynecologic malignancies, with an incidence of less than 1%. We report a case of primary fallopian tube carcinoma with a heterogeneous cell population showing pathways of differentiation toward both squamous cell carcinoma and adenocarcinoma.

From the Division of Gynecologic Oncology, Department of Obstetrics and Gynecology, and the Divisions of Surgical and Oncologic Pathology, Department of Pathology, University of North Carolina School of Medicine.

Supported in part by a grant from the Gaston County, North Carolina, Cancer Society Inc., and American Cancer Society Fellowship No. 86-132. Dr. Siegal is a Jefferson Pilot Fellow in Academic Medicine at the University of North Carolina School of Medicine.

Received for publication November 10, 1986; revised April 6, 1987; accepted May 5, 1987.

Case report

A 42-year-old white woman, gravida 2, para 1-0-1-1, presented with a 3-week history of left lower-quadrant abdominal pain, radiating into the left leg and a concomitant 7-pound weight loss. Pelvic examination revealed a 9 cm firm, exquisitely tender mass at the vaginal apex extending posteriorly toward the cul-de-sac and to the left of midline. Her past medical history was significant in that she had a total vaginal hysterectomy

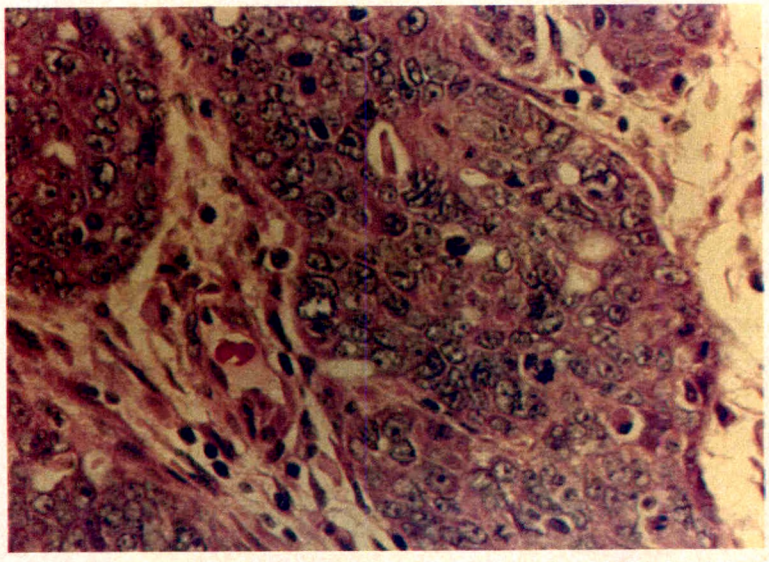

Fig. 1. Representative field of predominantly nonkeratinizing squamous cell carcinoma. Attempts at lumen formation are minimal. (Hematoxylin and eosin. Original magnification ×160.)

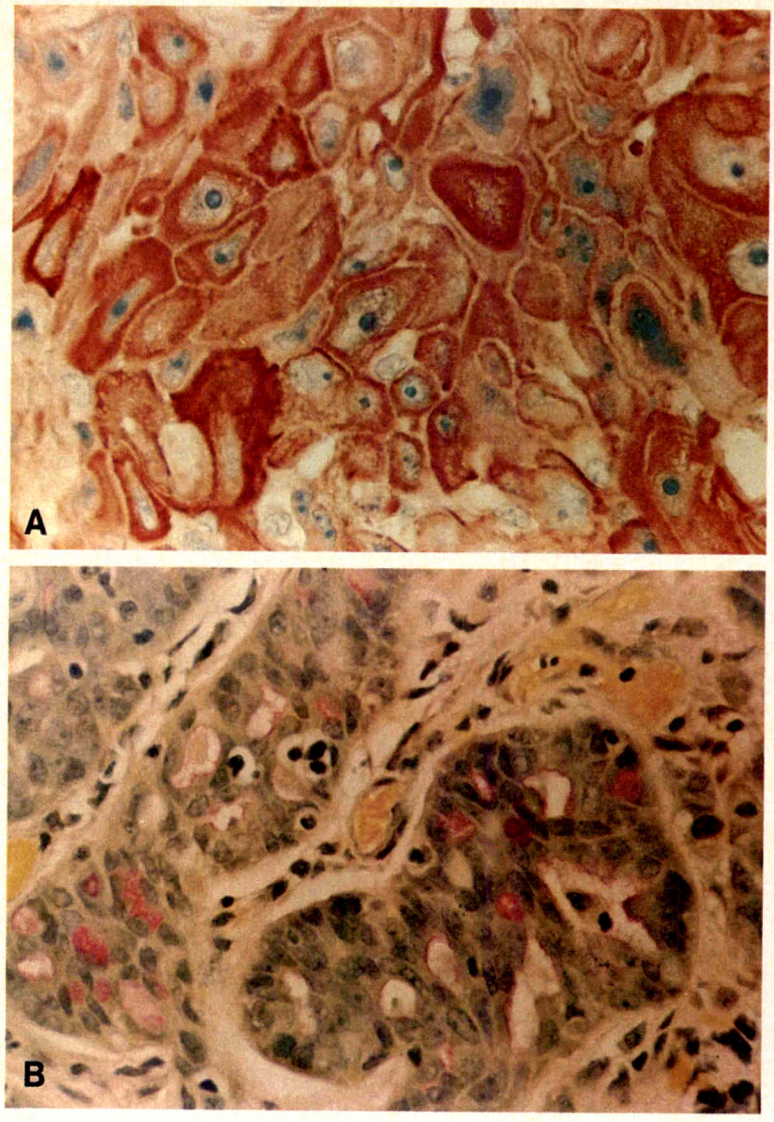

Fig. 2. *A*, Intense cytoplasmic immunoreactivity of keratinizing squamous neoplastic cells with polyclonal antibodies against keratin(s). (3,3′-Diaminobenzidine with hematoxylin counterstain. Original magnification ×250.) *B*, Intracytoplasmic and extracellular mucins are seen within islands of neoplastic cells similar to those demonstrated in Fig. 1. (Mucicarmine–metanil yellow. Original magnification ×160.)

performed 20 years earlier. Pathologic examination of the uterus revealed chronic cervicitis and squamous metaplasia of the endocervical epithelium.

The presence of a total leukocyte count of 23,300 cells/mm^3 in association with the findings described above led to a diagnosis of a pelvic abscess. She was treated with intravenous gentamicin and clindamycin. A pelvic computed tomographic scan showed an 8 by 9 cm "complex" left pelvic mass, without ascites or adenopathy. Other laboratory and radiologic studies were noncontributory. Her symptoms rapidly resolved with treatment and she was discharged on a regimen of a 1-week course of oral antibiotics. She was then readmitted for exploratory laparotomy, bilateral salpingo-oophorectomy, partial omentectomy, and pelvic and periaortic lymph node biopsies. A mass arising from the left adnexa and impinging on the sigmoid colon and cul-de-sac peritoneum was resected. She had an unremarkable postoperative course. Cytopathologic examination of peritoneal washings showed no evidence of malignant cells.

The left adnexal mass was an irregular, bosselated, spheroid structure (10 by 7 by 7 cm), appearing grossly to arise from the enlarged fallopian tube and expanding into the peritubal soft tissue. A normal-appearing left ovary was adherent to the surface of the mass.

Sections of the mass showed extensive necrosis with solid areas of moderately differentiated keratinizing

and nonkeratinizing neoplastic squamous cells (Figs. 1 and 2, *A*). The neoplastic cells were immunoreactive with antibodies directed against human stratum corneum (predominantly 56 and 64 kD) keratins (Immunon Corp., Troy, Michigan). Juxtaposed sections of the fallopian tube showed a lumen filled with a neoplasm with an "endometrioid" histologic pattern without evidence of squamous differentiation. These cells also demonstrated "positivity" with the antikeratins. Intracellular and extracellular mucins were identified histochemically (mucicarmine) and keratin was also found immunohistochemically at the site where the neoplasm extended out through the fallopian tube wall (Fig. 2). The sections of the ovary showed only superficial invasion by squamous cell carcinoma.

Transmission electron microscopy of the tumor showed both glandular and squamous differentiation. Intraluminal gland formation was prominently seen (Fig. 3). Intermediate filaments consistent with tonofilament (keratin) bundles along with desmosomes and microvilli were easily identified. The cytoplasm of the tumor cells contained prominent rough endoplasmic reticulum, glycogen, and amorphous material.

Comment

Fallopian tube malignancies, because of their rarity, are usually not diagnosed before definitive surgical treatment. In retrospect, most patients sought medical attention because of abdominal pain, a pelvic mass, or vaginal bleeding. Histologically, these tumors are almost always adenocarcinomas and are usually unilateral. However, like endometrial neoplasms, tubal adenoacanthoma has been reported. Mallinak et al.[1] reported a case of a pure tubal squamous cell carcinoma and Imm[2] described a tubal adenosquamous carcinoma on the basis of routine light microscopic observations.

Keratins are a family of at least 19 polypeptides that are organized as intermediate filaments in all epithelia. Many tumors, including squamous cell carcinomas and adenocarcinomas of the genitourinary tract, have been found to be immunoreactive under appropriate conditions of fixation and antibody selection. So-called endometrioid adenocarcinomas, as a group, are usually devoid of intracellular mucin. However, those arising in the fallopian tube have not been studied in large enough numbers for us to know if the positivity seen in our case is an exception to the usual rule. Our report confirms the existence of this entity and supports the concept that müllerian-derived epithelium can give rise to lesions with multipotential cytologic features in the fallopian tube.

We thank Dr. F. B. Askin for reviewing the histopathologic material.

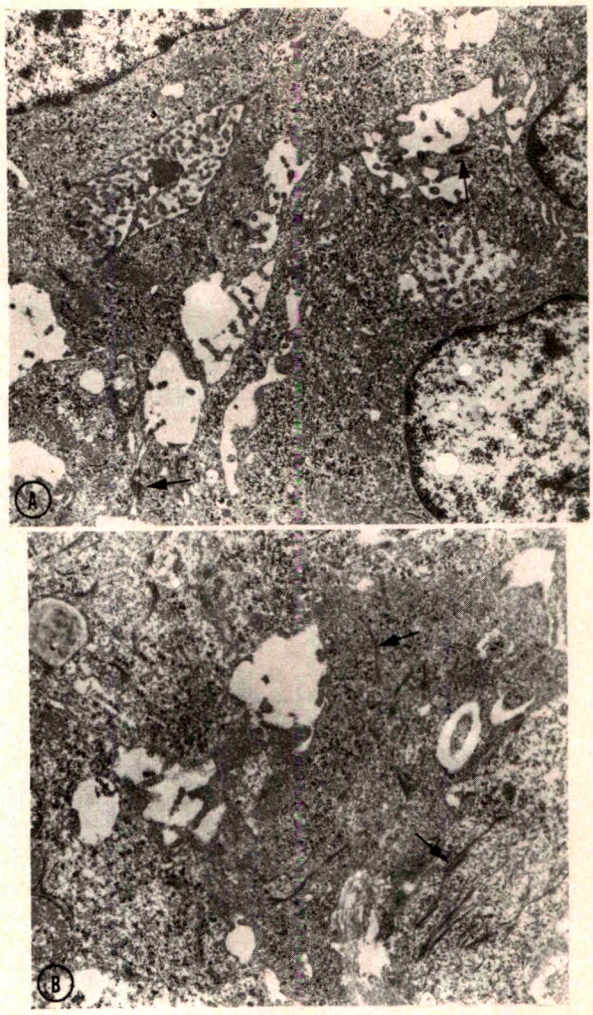

Fig. 3. Transmission electron micrograph demonstrating glandular lumina lined by microvilli. *A*, Well-formed desmosomes are appreciated at cell contact points *(arrows)*. (×6800.) *B*, A high-power view of the tonofilaments that were also present ultrastructurally in many cells throughout the tumor (×13,000.)

Addendum

After receiving two courses of cisplatin chemotherapy (50 mg/m^2), the patient was lost to follow-up for 5 months. She then presented with a histologically verified pelvic recurrence that was resected. No extrapelvic spread was identified at operation, and she is currently undergoing further cisplatin chemotherapy.

Increased tubular enzyme excretion in preeclampsia

Marshall P. Goren, M.D., Baha M. Sibai, M.D., and Adel El-Nazar, M.D.
Memphis, Tennessee

The pathophysiology of preeclampsia includes ischemia and microinfarctions of the kidney, which could induce renal tubular cells to release enzymes into urine. We therefore measured the concentrations of two markers of renal tubular damage, *N*-acetyl-β-D-glucosaminidase and alanine aminopeptidase, in urine specimens from women with mild or severe preeclampsia and compared the results with those from healthy pregnant and nonpregnant women. The median urinary concentrations of *N*-acetyl-β-D-glucosaminidase and alanine aminopeptidase in women without preeclampsia increased progressively through the first, second, and third trimesters and reached maximum values of 1.12 and 0.77 U/mmol creatinine, respectively. Median concentrations of the two enzymes were significantly higher in women with mild preeclampsia (*N*-acetyl-β-D-glucosaminidase = 1.40, alanine aminopeptidase = 1.12 U/mmol creatinine) or severe preeclampsia (*N*-acetyl-β-D-glucosaminidase = 2.90, alanine aminopeptidase = 1.26 U/mmol creatinine). This increased enzyme excretion indicates subclinical preeclamptic renal tubular damage. (AM J OBSTET GYNECOL 1987;157:906-8.)

Key words: Normal pregnancy, preeclampsia, *N*-acetyl-β-D-glucosaminidase, alanine aminopeptidase, renal tubules, urine

Preeclampsia-eclampsia is associated with high rates of maternal and fetal mortality and morbidity.[1] Hypertension and vasospastic ischemia leading to multiple microinfarctions of the brain, liver, and kidney are characteristic features of the disease.[2] Damage to these organs accounts for other common manifestations: edema, proteinuria, and cerebral dysfunction.

In the kidney, the classic lesion is glomerular endotheliosis. Renal tubular damage may also be a feature of preeclampsia. We have evaluated subclinical renal tubular damage in patients receiving anticancer drugs by monitoring the excretion of the renal enzymes *N*-acetyl-β-D-glucosaminidase and alanine aminopeptidase.[3-6] Since urinary levels of *N*-acetyl-β-D-glucosaminidase are increased in patients with renal artery stenosis[7] and essential hypertension,[8, 9] we reasoned that preeclampsia might similarly induce the release of enzymes from tubular cells into urine. By measuring urinary concentrations of *N*-acetyl-β-D-glucosaminidase and alanine aminopeptidase, we sought to quantify the extent of tubular damage in women with mild or severe preeclampsia.

Patients and methods

Urine specimens were obtained from healthy nonpregnant women and from healthy women in their first, second, and third trimesters of pregnancy. Specimens were also obtained from women who met the criteria for mild or severe preeclampsia.[1] Mild preeclampsia was defined as a rise in blood pressure that is 30 mm Hg systolic or 15 mm Hg diastolic above baseline readings on two separate occasions at least 6 hours apart. Severe preeclampsia was defined as the presence of blood pressure of 160/110 mm Hg on two separate occasions, 6 hours apart, accompanied by proteinuria with or without generalized edema.

Specimens were stored at 4° C and centrifuged to remove amorphous salts before analysis. The urinary concentrations of alanine aminopeptidase and *N*-acetyl-β-D-glucosaminidase, which were determined by automated spectrophotometric methods,[3, 10] were expressed relative to the urinary creatinine concentration to adjust for variations in urine output.[11]

The Kruskal-Wallis nonparametric analysis of variance test with adjustments for multiple comparisons as proposed by Nemenyi,[12] was used to compare median concentrations among groups of patients.

Results

The six study groups consisted of 10 nonpregnant women (mean age, 21.6 years ± 4.6 SD), 34 normotensive pregnant women in the first trimester (mean age, 19.3 years ± 3.9 SD), 26 in the second trimester (mean age, 18.3 years ± 4.2 SD), and 40 in the third trimester (mean age, 19.5 years ± 4.0 SD). Thirty women with mild preeclampsia (mean age, 18.7

years ± 4.1 SD) and 46 with severe preeclampsia (mean age, 19.1 ± 4.3 SD) were also in the third trimester. Gestation times did not vary significantly between women with preeclampsia and normotensive women in the third trimester, and all pregnant women were primigravidas. Two patients in the group with severe preeclampsia had thrombocytopenia, hemolysis, and elevated liver enzymes.

Fig. 1 shows urinary concentrations of *N*-acetyl-β-D-glucosaminidase and alanine aminopeptidase for women with preeclampsia compared with pregnant and nonpregnant control subjects. Enzymuria in healthy pregnant women was clearly increased over findings in nonpregnant women. The *N*-acetyl-β-D-glucosaminidase and alanine aminopeptidase levels showed progressive increases with gestation time; the median values for both markers in healthy third-trimester women were significantly higher than those for women in the first trimester ($p < 0.05$). The median *N*-acetyl-β-D-glucosaminidase and alanine aminopeptidase levels for women with mild or severe preeclampsia were significantly higher than the median value for healthy pregnant women in the third trimester ($p < 0.05$).

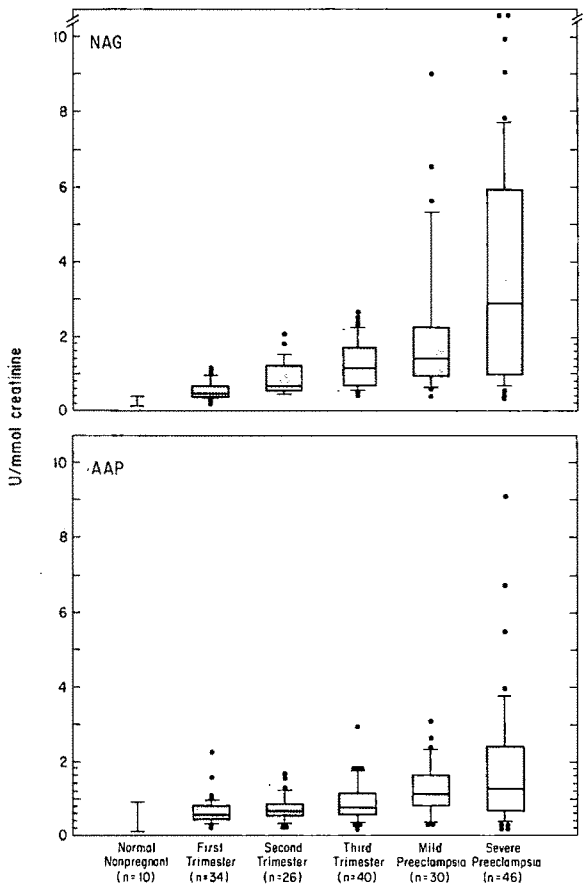

Fig. 1. Urinary *N*-acetyl-β-D-glucosaminidase *(NAG)* and alanine aminopeptidase *(AAP)* concentrations in women with preeclampsia and control subjects. For each category, the *shaded box* includes the median value *(bar)*, with ranges to the twenty-fifth and seventy-fifth percentiles; the *vertical bars* extend to tenth and ninetieth percentiles, with all other values shown individually. For nonpregnant women, the *vertical bar* indicates the range of values.

Comment

The increased excretion of *N*-acetyl-β-D-glucosaminidase and alanine aminopeptidase, as well as other enzymes,[11, 13] in pregnant women stems from normal changes in renal function that enhance the rate of enzyme turnover. However, *N*-acetyl-β-D-glucosaminidase levels in women with preeclampsia were higher than those associated with normal pregnancy or those reported in essential hypertension.[8, 9] The increased enzyme excretion in women with preeclampsia may reflect renal ischemia and relative hypertension of pregnancy. The striking enzyme excretion in some women with severe preeclampsia suggests a tubular lesion consonant with arteriolar constriction and microinfarction.

Many of the low values for *N*-acetyl-β-D-glucosaminidase and alanine aminopeptidase in women with preeclampsia in this study might be ascribed to fluctuations (intermittent vasospasms) in the intensity of the disease. Moreover, the diagnosis of preeclampsia is difficult to establish with certainty on clinical grounds alone.[12] However, patients with preeclampsia whom we studied were young primigravidas without any history of chronic hypertension or renal disease. Moreover, 68 of the 76 patients had normal blood pressures before 20 weeks' gestation. Hence, it can be argued that most of these patients had pure preeclampsia.

The overlap of values for *N*-acetyl-β-D-glucosaminidase and alanine aminopeptidase in women with preeclampsia with those for healthy women in the third trimester precludes any diagnostic use for single specimens. The clinical value of monitoring enzyme concentrations is limited to the detection of nonspecific tubular damage because excretion is increased in patients with other renal diseases and by administration of many drugs. Nevertheless, longitudinal monitoring of selected patients at risk of developing the disease may be of value for investigations of subclinical renal tubular ischemia. Ischemic tubular damage may precede the development of glomerular endotheliosis and clinically overt preeclampsia.

We thank Richard K. Dodge for statistical analyses and John Gilbert for editorial review.

Short course of antibiotics for post–cesarean section endometritis

Michael Cabbad, M.D., Odie Sijin, B.S., and Howard Minkoff, M.D.
Brooklyn, New York

Although post–cesarean section endometritis is a common postoperative complication, little has been reported on the safety of short-course therapy, particularly in indigent populations. Our preliminary data on 25 indigent patients with endometritis treated only until 24 to 36 hours after defervescence suggest that courses of antibiotics need not routinely be continued for 7 to 10 days. (AM J OBSTET GYNECOL 1987;157:908-9.)

Key words: Cesarean section, endometritis, antibiotics

Endometritis is one of the most common complications of cesarean section. Although modern antimicrobial therapy has helped to reduce the sequelae of infection, the increasing operative rate makes endometritis a continuing, common clinical problem. Much literature exists dealing with the relative merits of various antibiotic regimens, but little has been published on the appropriate duration of therapy.

The common practice of continuing antibiotics arbitrarily for 7 to 10 days (switching from parenteral to oral, if there is an oral equivalent, when the patient has been afebrile for 48 to 72 hours) has recently been questioned.[1] However, scant data have been reported concerning the safety and efficacy of shorter therapeutic courses of antibiotics. The data that have been published have not provided microbiologic information and have reported only on a generally "healthy" population, leaving open the question of the utility of this approach in indigent populations in whom infection rates are generally higher and host resistance potentially reduced.[2] In an attempt to assess the safety of a short course of antibiotics in an indigent population with defined pathogens, we evaluated 25 service patients diagnosed as having post–cesarean section endometritis (uterine tenderness and standard fever).

Material and methods

Patients were black and Hispanic and of lower socioeconomic status (either medicaid or no insurance). Endometrial cultures were obtained in all patients with triple-lumen catheters before initiation of single-agent

antibiotic therapy (imipenem, 500 mg every 8 hours). Patients were treated with intramuscular medication until they had been afebrile for 24 to 36 hours. No follow-up oral medications were given. All patients underwent final evaluations 4 to 6 weeks after discharge.

Results

Pretherapy cultures yielded 53 isolates, 38 of which were high virulence. Twenty-one of the 25 patients responded to imipenen alone. One patient had phlebitis, one had a bladder flap hematoma, and two required additional antibiotics before defervescence. In all cases therapy was discontinued 24 to 36 weeks after the patient had been afebrile. The mean duration of therapy, including primary treatment failures, was 4.4 days. However, what is most important is that 16 of 25 patients required 4 or fewer days of antibiotics whereas only the four patients for whom treatment failed required therapy beyond 5 days. Thus 65% of patients received less antibiotics then they would have if therapy had been given routinely for 5 or more days. Further, 13 patients completed the course of treatment on the fourth or fifth postoperative day. If the course of antibiotics had been extended to complete a predetermined course, the hospital stay would have had to be prolonged (there is no oral equivalent for imipenem).

All patients were well on discharge and at the time of follow-up. There were no readmissions.

In an article summarizing post–cesarean section endometritis, Duff[1] wrote, "Parenteral therapy should be continued for 24 to 48 hours after the patient becomes afebrile and asymptomatic. At this point antibiotics may be discontinued." Despite the common sense of this advice, at the time it was written no documentation of the safety of a shortened course of antibiotics existed. Indeed, studies comparing the efficacy of various therapeutic regimens frequently advised continuing antimicrobials for an arbitrary period independent of the time of defervescence. The need to heed Duff's advice is heightened at a time of increased scrutiny of medical care costs that would be clearly raised by courses of antibiotics continued for 7 to 10 days rather than the 4.4 days used in this study. This would be especially problematic if the antibiotic used had no oral equivalent in which case hospital stay also might be prolonged. In 1987 Soper et al.[2] documented the safe application of a short course of antibiotics in a dependent military population. They cautioned that the applicability of their approach to an indigent population needed to be tested. Further, no microbiologic data were provided to document infection with high-virulence organisms. Our preliminary report confirms their findings and suggests that their conclusions may also be applicable in an indigent population infected with high-virulence organisms. Clearly larger numbers of patients need to be examined, but our initial data support the call of Duff and Soper et al. for shorter courses of therapeutic antibiotics.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

First-trimester serum levels of the β-subunit of human chorionic gonadotropin in a tubal molar pregnancy

Jeffrey S. Chase, M.D., Jerome H. Check, M.D., Khosrow Nowroozi, M.D., and Chung H. Wu, M.D.

Philadelphia, Pennsylvania

A woman is described in whom the levels of the β-subunit of human chorionic gonadotropin were rising in a pattern consistent with a tubal pregnancy. A tubal molar pregnancy was found. Thus an early ectopic molar pregnancy is not distinguishable from a nontrophoblastic tubal pregnancy on the basis of human chorionic gonadotropin levels. (Am J Obstet Gynecol 1987;157:910.)

Key words: Tubal molar pregnancy, human chorionic gonadotropin

Frequently the serum human chorionic gonadotropin (hCG) β-subunit levels in ectopic pregnancy do not show an appropriate doubling time.[1] The hCG β-subunit levels in patients with gestational trophoblastic disease are generally higher than anticipated for conceptual dating.[2] A case is presented of a tubal molar pregnancy, in which serial hCG titers were closely monitored shortly after conception. The levels were not distinguishable from hCG patterns seen in ectopic gestations of nontrophoblastic proliferation.

Case report

A 38-year-old nulligravid woman with a history of long-term infertility and oligomenorrhea had ovulation induction with clomiphene citrate, 50 mg, on days 5 to 9. Two mature follicles of 18.3 mm (right ovary) and 19.3 mm (left ovary) formed, and the functional maturity of those follicles was evidenced by a serum estradiol level of 655 pg/ml with a serum progesterone level of 0.3 ng/ml. Release of the ova from the follicles was also documented by sonography. The patient presented 5 weeks after the documented release of the ova but the hCG β-subunit level was only 83 mIU/ml. However, the hCG level proceeded to rise such that 9 days later it was 883 mIU/ml. It then rose to 903 mIU/ml 4 days later and reached a peak of 3347 mIU/ml 19 days later. At this time a pelvic ultrasound evaluation failed to reveal a gestational sac and instead demonstrated a 16 by 12 by 13 mm echo-free area in the right adnexa with no free fluid seen. A diagnostic laparoscopy revealed a leaking right tubal pregnancy involving the right proximal and mid ampullary segment. The left adnexa appeared totally within normal limits and at this point a right partial salpingectomy was performed. The pathologic diagnosis on the resected tubal segment revealed hydatidiform mole with moderate trophoblastic proliferation arising in the ectopic pregnancy within the tube. Pathologic consultation was requested from a member of the trophoblastic disease registry who also reached a similar diagnosis, hydatidiform mole arising in an ectopic (oviductal) gestation and chronic salpingitis. The patient's postoperative course was uneventful and she permitted determination of only two follow-up hCG levels: 10.6 mIU/ml 13 days after operation and <5 mIU/ml 21 days after operation.

Comment

The failure to show appropriate doubling time of the hCG β-subunit level, from an initial value of 83 mIU/ml to only 903 mIU/ml 14 days later, is consistent with a typical pattern seen with tubal pregnancy. Thus, had the day of conception not been known, the interpretation of these hCG levels would not make one suspicious of trophoblastic disease. However, the marked rise in the hCG β-subunit level despite a previous low level of 83 mIU/ml 5 weeks after conception (which had suggested spontaneous abortion) created great suspicion of trophoblastic proliferation.

After 55 days from conception an appropriate interval doubling of the hCG β-subunit was seen for the first time and one can only speculate that had there not been surgical intervention that a more rapid inappropriate elevation of the hCG levels might have been noticed.

Pregnancy in Henoch-Schönlein purpura

Geetha Joseph, M.D., James S. Holtman, M.D., Rodney E. Kosfeld, M.D., William A. Blodgett, M.D., and Yong K. Liu, M.D.

Louisville, Kentucky

A 22-year-old white woman with Henoch-Schönlein purpura was treated with frequent plasmapheresis for increased severity of the disease activity during pregnancy. Hypertension, azotemia, and placental dysfunction were not observed. A healthy infant was delivered by cesarean section, and evidence of vasculitis was not detected in the placenta. (Am J Obstet Gynecol 1987;157:911-2.)

Key words: Pregnancy, Henoch-Schönlein purpura, plasmapheresis

Henoch-Schönlein purpura is a clinical syndrome of generalized vasculitis manifested by purpuric skin rash, hematuria, proteinuria, abdominal pain, gastrointestinal bleeding, and arthralgias. The treatment of Henoch-Schönlein purpura, including the use of corticosteroids, has been unrewarding. Plasmapheresis has been tried in a few patients for deteriorating renal failure with varying success.

Very little is known about pregnancy in Henoch-Schönlein purpura. Thus far, only two women with Henoch-Schönlein purpura during pregnancy have been described.[1,2] We describe herein the successful use of frequent plasmapheresis for the treatment of recurrent and severe attacks of Henoch-Schönlein purpura during pregnancy.

Case presentation

A 22-year-old white nulliparous woman was admitted to the hospital in January 1982 with nausea and abdominal pain. There was no rash, fever, or gastrointestinal bleeding. Results of laboratory studies were normal except for proteinuria and hematuria. Ultrasonography of the abdomen revealed gallstones. Symptomatic relief was achieved after cholecystectomy 4 months later.

In February 1983, she was hospitalized with a 2-week history of purpura, fever, abdominal pain, and hematuria. She denied joint pain, melena, or headache. Crops of nontender palpable purpura, 1 to 3 mm in diameter, were present on the abdomen and legs associated with right upper quadrant tenderness. Urinalysis revealed a trace of protein and 75 to 100 erythrocytes but no leukocytes. Routine chemistries, blood cell count, and coagulation test results were normal. The skin biopsy specimen revealed leukocytoclastic vasculitis with immunoglobulin G and immunoglobulin M deposits. Circulating immune complexes were elevated (43.5 μg antihuman globulin Eq/ml by Clq binding assay); C3, C4, and CH-100 were low. A clinical diagnosis of Henoch-Schönlein purpura was made. A 2-week trial of steroids resulted in no symptomatic improvement. Subsequently, her symptoms gradually subsided but recurred in June 1983. Plasmapheresis with removal of 2 L plasma and replacement with 1 L normal saline solution and 1 L 5% albumin was performed on 2 consecutive days. The abdominal pain responded promptly to the first plasmapheresis and no new purpura appeared after the second.

The patient was admitted to the hospital six more times in the next 22 months and was treated with plasmapheresis each time with rapid symptomatic improvement. She remained symptom free between relapses but microscopic hematuria persisted.

The patient became pregnant in April 1985 and soon thereafter had two severe relapses requiring up to 12 consecutive daily episodes of plasmapheresis to control her symptoms. Severe exacerbations recurred in the fifth and sixth months of gestation and were treated successfully with plasmapheresis. At 28 weeks of gestation, cramping lower abdominal pain simulating premature labor occurred without purpura. This spontaneously subsided during observation. At 37 weeks of gestation, cesarean section was performed to avoid the potential difficulty of differentiating relapse of Henoch-Schönlein purpura from other intra-abdominal conditions. A healthy female infant weighing 2700 gm was delivered. The placenta showed no vasculitis or infarction Despite persistent macroscopic hematuria, her blood pressure and renal function remained normal throughout the pregnancy.

The effect of pregnancy on the course of Henoch-Schönlein purpura remains unclear, and the treatment of relapses during pregnancy is unknown. Of the two

reported cases, Plauche[1] first described a 19-year-old nulliparous woman who became pregnant 6 months after an episode of purpura, hematuria, and abdominal pain. Hypertension, azotemia, and worsening proteinuria necessitated cesarean section at 30 weeks of gestation with delivery of a viable infant. There was no recurrence of Henoch-Schönlein purpura during the pregnancy. McCoy[2] reported a 21-year-old nulliparous woman with purpura, fever, arthralgia, and abdominal pain at 17 weeks of gestation. The symptoms remitted in 2 weeks without any therapy and the rest of her pregnancy was uneventful. A viable infant was delivered vaginally at term. No information on changes in the placenta was available on either patient.

The patient reported herein appears to have a more severe form of Henoch-Schönlein purpura. Relapses became more frequent and severe during pregnancy and were treated with multiple episodes of plasmapheresis without adverse effect. Similarly, plasmapheresis has been used in the treatment of myasthenia gravis and Rh immune diseases during pregnancy without untoward effect. Steroids were not used. This procedure may be useful for symptomatic treatment of Henoch-Schönlein purpura in pregnancy.

Theca-lutein ovarian cysts associated with homozygous α-thalassemia

Philip D. Miller, M.D., Brenda C. Smith, M.D., and David N. Marinoff, M.D.
Santa Clara, California

We present a case of theca-lutein cysts associated with homozygous α-thalassemia. Theca-lutein cysts have been associated with various types of nonimmune hydrops fetalis but have not been reported previously in association with homozygous α-thalassemia. (Am J Obstet Gynecol 1987;157:912-4.)

Key words: Thalassemia, theca-lutein cysts

Theca-lutein cysts of the ovary are most commonly associated with hydatidiform moles and choriocarcinoma. These cysts have been reported less commonly as a finding in nonimmune hydrops fetalis.[1] It is believed that theca-lutein cysts associated with nonimmune hydrops fetalis are caused by the highly elevated levels of human chorionic gonadotropin (hCG) produced by the enlarged hydropic placenta. The causes of nonimmune hydrops fetalis are many; more than 70 causes have been identified, including homozygous α-thalassemia.[2] We describe a patient with nonimmune hydrops fetalis caused by homozygous α-thalassemia and accompanied by large, bilateral theca-lutein cysts. This findings, first noted ultrasonographically during the third trimester of pregnancy, added a confusing dimension to our patient's clinical condition and care.

Case report

A 28-year-old Vietnamese woman, gravida 1, para 0, was admitted to the Kaiser Permanente Medical Center, Santa Clara, California, at 30 weeks' gestation with clinical signs of preeclampsia. Physical examination showed blood pressure of 130/90 mm Hg and pretibial edema (2+). The uterus measured 34 cm in height. A rapid increase in fundal size had been noted over the previous 2 weeks. The cervix was closed with the vertex unengaged. Laboratory findings included a uric acid level of 11.0 mg/dl. All other values, including those for serum creatinine, blood urea nitrogen, serum glutamic oxaloacetic transaminase, complete blood count, platelet count, and glucose tolerance, were normal.

Ultrasound examination showed multiple abnormal findings. Polyhydramnios and a markedly enlarged placenta were present. Fetal findings included cardiomegaly, pericardial effusion, and hepatomegaly. No ascites or scalp edema was seen. Ultrasound scan also revealed large bilateral adnexal cystic masses measuring 5 by 7 cm each with alternating areas of cystic and solid material. Placental size and ultrasonographic findings induced us to search for a possible source of intra-

uterine infection or other cause of possible hydrops fetalis. Blood type was B, Rh-positive. Results of a VDRL test were nonreactive. Rubella and toxoplasmosis titers were negative. Cytomegalovirus titers were positive at 1:2169 dilutions and a herpes simplex titer was also positive at 1:1600 dilutions. Hematocrit was 38%. Mean corpuscular hemoglobin volume was noted to be 71 μm^3. The husband's complete blood count showed a mean corpuscular volume of 68.3 μm^3 (normal range >80 μm^3). The suspected diagnosis at that time was fetal homozygous α-thalassemia.

The patient's hospital course changed quickly with rapidly increasing polyhydramnios. Serial ultrasound scans done after admission to the hospital showed worsening fetal cardiomegaly. A nonstress test of the fetus showed an ominous pattern; that is, loss of short- and long-term variability and late decelerations were seen during a contraction stress test.

Because of the bilateral ovarian cysts, it was decided to perform an exploratory operation to rule out ovarian malignancy; this was done before death in utero occurred. A cesarean section was done to deliver the baby and to explore the abdominal cavity.

At operation, a 1290 gm infant was delivered and died in the delivery room. Bilateral theca-lutein ovarian cysts measuring 6 by 7 cm were found at operation. Biopsy of the left ovary showed typical changes in the theca-lutein cysts. The ovaries were then carefully returned to the abdominal cavity so as not to twist or rupture them. The placenta weighed 1600 gm.

The patient had an uneventful recovery from operation. Umbilical cord hemoglobin was evaluated (East Bay Cord Blood Screening Program for Hemoglobinopathies, Alta Bates Hospital, Berkeley/Children's Hospital, Oakland, California) and showed only Bart's hemoglobin, consistent with homozygous α-thalassemia. The β-subunit of hCG of the mother was studied serially in an attempt to explain the presence of theca-lutein cysts. The initial titer of the β-subunit of hCG was 1,120,000 mIU/ml. This level fell to 83.8 mIU/ml 15 days after operation and to <3 mIU/ml 5 weeks after delivery. No ovarian enlargement was palpable at examination 6 weeks after delivery. Ultrasound examination at this time confirmed that the ovaries were of normal size.

Comment

Theca-lutein cysts are usually found in association with hydatidiform moles or choriocarcinoma, suggesting that elevated secretion of trophoblastic hCG is responsible. Thecal luteinization and cyst formation may be caused by increased cystic atresis or by a heightened ovarian response to normal or elevated hCG levels. A correlation has also been demonstrated between elevated serum levels of hCG and hydrops fetalis. In such cases, the placentas are greatly enlarged, probably representing a source of increased hCG secretion.

A variety of conditions may give rise to hydrops fetalis, including Rh isoimmunization (a well-known cause), twin-twin transfusion syndrome, and many types of nonimmune hydrops, frequently idiopathic. The most frequent cause of hydrops fetalis in the Southeast Asian population is now recognized to be homozygous α-thalassemia or Bart's hemoglobinopathy. This condition is due to deficient α-globulin chain synthesis and is inherited as an autosomal recessive trait. Because of its high oxygen affinity, Barty's hemoglobin is useless as an oxygen carrier; the fetus therefore develops hydrops fetalis as a result of high-output cardiac failure. Homozygous α-thalassemia is incompatible with extrauterine life.

Our patient's pregnancy showed typical signs of Bart's hemoglobinopathy, that is, presence of mild microcytic anemia in the mother (low mean corpuscular volume unresponsive to iron therapy). Hydramnios and pregnancy-induced hypertension also commonly develop late in the second trimester or early in the third trimester. Intrauterine death from high-output cardiac failure is usually seen. The father, who was Asian, had similar blood test results, which showed mild anemia and a low mean corpuscular volume. Affected fetuses, as in this case, typically have cardiomegaly, frequently have ascites, and sometimes have pericardial effusion and hepatosplenomegaly caused by extramedullary hematopoiesis.

Since the α-thalassemia heterozygote produces no recognizable phenotype, detection requires careful screening, especially of indices in red blood cell morphologic analysis. Patients with a low mean corpuscular volume should be checked for iron-deficiency anemia and, if this is absent, hemoglobin electrophoresis should be performed. Normal hemoglobin electrophoresis results, normal iron stores, and low mean corpuscular volume are consistent with the α-thalassemia trait. Partner screening can then be done to evaluate the risk that offspring will have Bart's hemoglobinopathy of homozygous α-thalassemia. Identification of the trait allows genetic counseling of the couple as well as screening of their children at risk. This strategy is of importance in areas of the United States that have large Asian populations and should be part of the genetic and obstetric treatment plans of physicians practicing in these areas.

We have reported the association of large theca-lutein cysts and high levels of the β-subunit of hCG in a woman carrying a child with Bart's hemoglobinopathy. Two bilateral cystic ovarian structures shown ultrasonographically led to surgical exploration in the patient, who had a poor fetal prognosis. The nature of the ovarian cysts was recognized at operation and the cysts were not excised. This is essential because excision of these large ovarian tumors can result in loss of reproductive potential for the patient if the cysts are not recognized as being benign theca-lutein cysts. This pos-

sibility must be considered when any abdominal operation is done in a pregnant woman in order to avoid removing normal ovaries.

The association of theca-lutein cysts with hydrops fetalis is an uncommon finding. We report it here because, when hydrops fetalis is recognized in association with bilateral ovarian cysts, the association is most likely due to large theca-lutein cysts, and conservative management is indicated. The size of the placenta, as well as serum hCG levels, may also help diagnose this condition so that surgical exploration may be avoided.

Racial differences in survival of women with endometrial cancer

Raymond P. Bain, Ph.D., Raymond S. Greenberg, M.D., Ph.D., and Kevin C. Chung, B.A.
Atlanta, Georgia

The hypothesis that white women with endometrial cancer survive longer than black women with this disease was evaluated in a retrospective analysis of a population-based, prospective cohort study. All female residents of metropolitan Atlanta with a first diagnosis of primary endometrial cancer from 1978 through 1982 were eligible for inclusion. The 628 white and 105 black women were followed up through June 1984 to determine survivorship. Race was evaluated as a prognostic factor with univariate, multivariate, and excess death rate analyses. Overall, an estimated 89.2% of whites and 61.6% of blacks survived 3 years from the time of diagnosis. Although black women tended to have more advanced disease at the time of diagnosis and a higher proportion of undifferentiated malignancies, the racial difference in survival persisted after adjustment for these factors. When initial therapy was considered, race remained a significant prognostic determinant among women who did not receive radiation therapy. (AM J OBSTET GYNECOL 1987;157:914-23.)

Key words: Survival, race, endometrial neoplasms, prognosis, mortality

Analyses of data collected by the National Cancer Institute concerning women diagnosed with cancer of the uterine corpus have repeatedly demonstrated inferior survival experiences for black women.[1-4] For patients diagnosed between 1973 and 1979, the 5-year relative survival rate for blacks (56%) was lower than that for Hispanics (87%) and American Indians (68%), which suggested that the effect was not entirely attributable to socioeconomic status.[3]

The conclusions reached in these surveys were limited in several respects. First, no adjustment was made for racial disparities in the distributions of histologic types. Second, no adjustment was made for possible racial differences in the distributions of histologic grades. Third, the broad categories used to characterize the extent of disease (e.g., localized versus others) may not have provided adequate control for racial dissimilarities in the stage of disease at the time of diagnosis. Finally, none of the analyses incorporated information on the types of treatments that were administered.

The purpose of the present investigation was to evaluate racial differences in survival of women with cancer of the endometrium. Analyses were adjusted for the effects of other prognostic factors, including age, marital status, socioeconomic status, histologic grade, stage of disease, and type of initial treatment.

Methods

The data for this study were collected by the Georgia Center for Cancer Statistics, an affiliate of the Surveillance, Epidemiology, and End Results Program. This registry is responsible for obtaining information on all

From the Departments of Community Health and Biometry, Emory University School of Medicine.
Supported in part by Contracts NO1-CN-61027 and NO1-CN-55429 from the National Cancer Institute.

incidences of cancer among residents of metropolitan Atlanta.[5]

Eligibility for inclusion in this study was limited to black or white female residents of the catchment area with an endometrial cancer diagnosed between Jan. 1, 1978 and Dec. 31, 1982. This accrual period was chosen because the most detailed information on the extent of disease was collected during those 5 years. The study population included 628 white women and 105 black women. The most common histologic type was adenocarcinoma (whites, 85.0%; blacks, 81.9%), followed by adenosquamous carcinoma (whites, 5.4%; blacks, 15.2%).

The primary method of case identification was the review of records at each of 37 hospitals and clinics in and around metropolitan Atlanta. Of the white women with endometrial cancer, 99.7% were identified from hospitalizations compared with 100% among black women. For both races, less than 0.1% of cases were registered from death certificates, which indicates that virtually all of the study population had a disease that was recognized clinically before the time of death.

Data were collected by a staff of trained medical record abstractors. Records were not abstracted until at least 4 months after the time of diagnosis to allow an assessment of the first course of medical treatment. Information about demographic, clinical, morphologic, and therapeutic variables was transcribed onto standard data collection forms, edited for completeness and internal consistency, coded following the guidelines of the Surveillance, Epidemiology, and End Results Program,[6] and entered into a computerized data base.

The demographic factors considered in this investigation were race (black versus white), age (years), marital status (married versus unmarried), and county of residence (Fulton county versus all others). The county of residence was used as an indicator of socioeconomic status, since Fulton County includes twice the percentage of persons living below the poverty level as found in the surrounding four suburban counties.[7] A more direct adjustment for socioeconomic status was not possible since data on income and education were not collected by the registry.

The tumor characteristics included the following: histologic grade of tumor (I = highly differentiated, II = moderately differentiated, and III = undifferentiated), depth of invasion (four ordinal categories; 1 = endometrium only, 2 = inner half of myometrium, 3 = outer half of myometrium, and 4 = invasion of serosa or extension into parametrium), evidence of cervical extension (present versus absent), and evidence of extrauterine involvement (present versus absent). Cervical extension was determined from the pathology reports when available. If a pathology report was unavailable, the clinical evaluation was used to characterize cervical extension (3%). Extrauterine involvement was defined as having at least one of the following present: direct extension of tumor beyond the uterus and parametrium, regional lymph node involvement, lymph node involvement outside of the pelvis, or distant site involvement. Extrauterine involvement was determined from the pathology reports or clinical evaluation.

Information about the first course of medical treatment included the following: surgical intervention (done or not done), type of surgical procedure performed, and radiation, hormone, and chemotherapy (each done or not done). In the present context, radiation therapy was defined as radiation treatment (preoperative and/or postoperative), with or without hormone and/or chemotherapy. Other therapy was defined as receiving hormone and/or chemotherapy.

Patients were followed up for vital status through the first half of 1984. The primary sources of information about survival were hospital records, which were supplemented by the records of private physicians and the quarterly review of computerized death certificates for the State of Georgia. Of the subjects who were known to be alive before 1982, 535 (97.3%) of the white women and 57 (95.0%) of the black women had a subsequent determination of vital status, which indicated small losses to follow-up.

The relationship between race and each of the other suspected prognostic factors was assessed by means of point estimates of the odds ratios and corresponding large sample approximate 95% confidence limits.[8] With death from cancer as the outcome, a univariate survival analysis was performed separately for each suspected prognostic factor by means of the Kaplan-Meier product limit estimator.[9] A generalized Wilcoxon test[10] was used to assess the statistical significance of differences between pairs of survival curves. With death from cancer as the outcome, the Cox proportional hazards regression model[11] was also used to evaluate the prognostic effect of race, with simultaneous adjustment for the effects of other prognostic factors.

To control for racial differences in expected deaths and avoid any possible bias from differential misclassification of causes of death, an excess death rate analysis was performed. For each racial group, the observed number of deaths from all causes was compared with the number of deaths expected from the woman-years of follow-up and the corresponding age, race, and sex-specific mortality rates for Georgia.[12] The excess death rate for each racial group was calculated as the difference between the observed and expected numbers of deaths per 1000 woman-years of follow-up.[13] A test statistic with a distribution that approximated a standardized normal deviate was used to assess the statistical significance of racial differences in excess death rates.[13]

Results

Relationship between race and other suspected prognostic factors

Demographic and tumor characteristics. The racial differences in demographic and tumor characteristics within the study population are summarized in Table I. The mean age ± standard deviation for black women was 64.1 ± 12.4 years (range: 26 to 89 years) compared with 62.2 ± 10.6 years (range: 25 to 97 years) for white women. The black women with endometrial cancer were significantly more likely to be unmarried and live in Fulton County.

Analysis of tumor characteristics indicated that black women had higher percentages of cervical and extrauterine involvement. Among women with recorded histologic grades (83%), the black women tended to have higher grades (I, 21%; II, 42%; and III, 37%) than those of white women (46%, 33%, 21%, respectively). Among women with depth of myometrial invasion information (84%), there was no racial difference in the percentage of women with invasion of the outer half of the myometrium or beyond.

Each of the demographic and tumor characteristics had less than 2% missing information except for histologic grade (17%) and depth of myometrial invasion (16%). There was no racial difference in the percentage of missing information for histologic grade (white, 16%; black, 18%, p = 0.67). The percentage of missing information for depth of myometrial invasion was greater (p = 0.02) for blacks (24%) than for whites (15%).

Distribution of treatments. Of the women with endo-

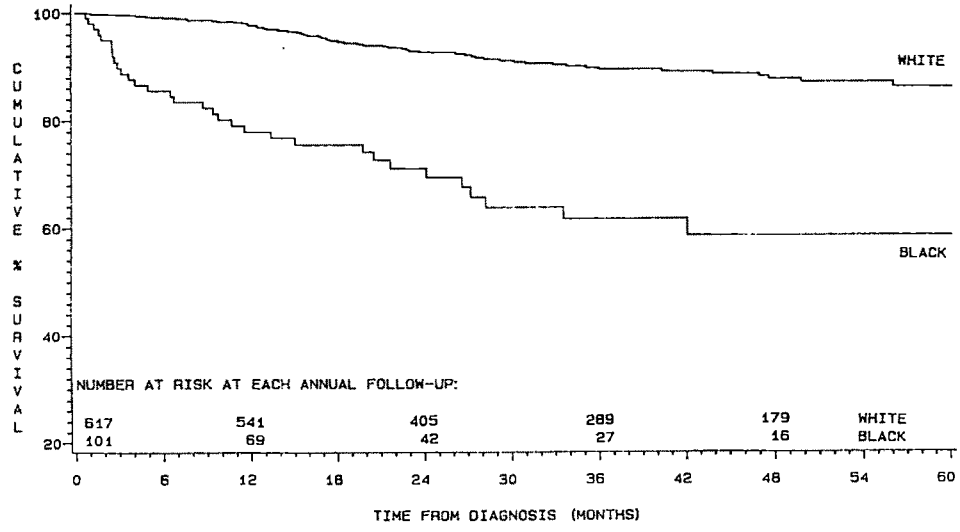

Fig. 1. Survival of women with endometrial cancer by race.

metrial cancer, 581 (79%) had surgery and 300 (41%) had radiation therapy. Since treatment could have been influenced by demographic and tumor characteristics, the distribution of treatments is presented in Table II by prognostic group and race for women 85 years of age and younger. Women with no cervical extension and no extrauterine involvement and a histologic grade of I or II were considered to have a favorable prognosis (i.e., Stage I disease with a differentiated neoplasm). All other women were considered to have unfavorable prognosis (i.e., Stages II through IV and/or an undifferentiated malignancy). For women without a recorded histologic grade, disease prognosis was determined by the stage of disease. For women less than or equal to 85 years of age at the time of diagnosis, 30% were classified as having unfavorable disease (white, 27%; black, 52%).

As indicated in Table II, the white women had significantly more surgery compared with black women (Mantel-Haenszel $\chi^2 = 5.51$, df = 1, p = 0.02). For women with favorable disease, 85% of the whites and 78% of the blacks had surgery. Within the unfavorable disease group, surgery was performed on 74% of the whites compared with 58% of the blacks. The racial difference in the percentage of women who received radiation therapy in addition to surgery was not uniform across the prognostic categories (test for homogeneity: $\chi^2 = 7.91$, df = 1, p = 0.005). As indicated in Table II, the blacks with favorable prognoses received more adjuvant radiation treatment compared with whites (50% for blacks and 33% for whites). Within the unfavorable category, 71% of white women received adjuvant radiation therapy compared with 52% among black women.

Univariate survival analysis. The relationship between race and survival in women with endometrial cancer is depicted in Fig. 1. Women older than 85 years of age at the time of diagnosis (10 whites and two blacks) and/or women with the date of diagnosis equal to the date of last follow-up (three whites and two blacks) were not included in any univariate survival analysis. The median follow-up time for the 617 white women was 34.1 months (range: <1 to 76.3 months) compared with a median follow-up time for 101 black women of 20.5 months (range: <1 to 77.1 months). For deaths caused by endometrial cancer, the product limit survival curve for white women was significantly ($p < 0.001$) higher than the corresponding survival curve for black women. For instance, 36 months after diagnosis, the cumulative percentage of survivors was 89.2% among whites but only 61.6% among blacks.

The univariate survival analyses of other demographic, treatment, and tumor characteristics are summarized in Table III. Women less than or equal to 60 years of age at the time of diagnosis, married women, and those residing outside of Fulton County had significant ($p < 0.005$) survival advantages.

All of the tumor and treatment characteristics except adjuvant radiation therapy were univariate predictors of survival ($p < 0.001$). Survivorship was associated with low histologic grade (I or II), depth of invasion limited to the endometrium or inner half of the myometrium, the absence of either cervical or extrauterine involvement, and having surgery performed.

Multivariate survival analysis

Demographic and tumor characteristics. The demographic and tumor characteristics were analyzed together to determine which variables were independent predictors of survival. The variables analyzed were race (1 = black), age at diagnosis (years), marital status

*Includes demographic and tumor characteristics only.
†Includes demographic, tumor, and treatment characteristics.
‡NS = not statistically significant (p > 0.10).

(1 = unmarried), county of residence (1 = Fulton), histologic grade (characterized by two indicator variables: grade I = 0,0; grade II = 1,0; grade III = 0,1), depth of myometrial penetration (four ordinal categories), cervical extension (1 = present), and extrauterine involvement (1 = present).

Before demographic and tumor characteristics were tested for statistical significance as independent predictors of survival, possible interactions between race and each of the other individual characteristics were examined by means of the Cox proportional hazards regression model. None of the interaction terms was significant (p > 0.20).

In recognition of the high percentage of women with missing data (30%) on either histologic grade or depth of myometrial invasion and the association between his-

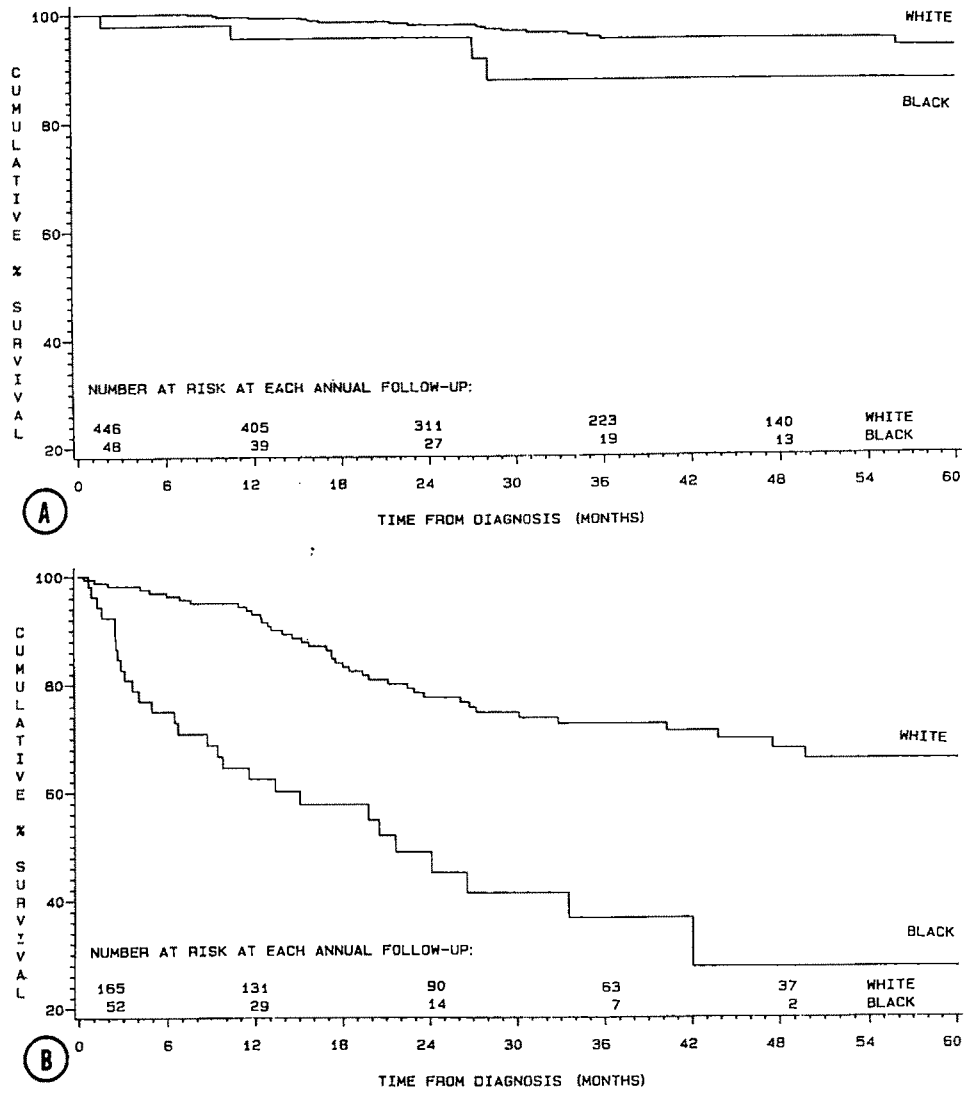

Fig. 2. A, Survival of women with favorable endometrial cancer by race. **B,** Survival of women with unfavorable endometrial cancer by race.

tologic grade and depth of invasion (test for independence: $\chi^2 = 42.8$, df = 4, $p < 0.001$), the Cox proportional hazards regression model was estimated separately with and without histologic grade or depth of myometrial invasion as predictors of survival. The total number of women less than or equal to 85 years of age at the time of diagnosis with complete information on all demographic and tumor characteristics except for histologic grade and depth of myometrial invasion was 702 (97%).

For these 702 women, the estimated hazard rate ratio (hazard rate of a black woman divided by the hazard rate of a white woman) unadjusted for the other demographic and tumor characteristics was 4.64, with 95% confidence limits of 2.98 and 7.20. In other words, the unadjusted rate of death among black women was elevated more than fourfold over the death rate for whites. Race was a significant ($p < 0.001$) predictor of survival after adjustment for the other demographic and tumor characteristics. The estimated hazard rate ratio after adjustment for age at diagnosis, marital status, county of residence, cervical extension, and extrauterine involvement was 3.57, with 95% confidence limits of 2.22 and 5.72.

The estimated regression model that used the demographic and tumor characteristics including histologic grade is presented as model 1 in Table IV. The total number of women less than or equal to 85 years of age with complete information was 588 (82%). The estimated unadjusted hazard rate ratio (blacks compared with whites) of the 588 women was 5.25, with 95% confidence limits of 3.33 and 8.49. In model 1, race was a significant ($p < 0.001$) predictor of survival after adjustment for the other demographic and tumor

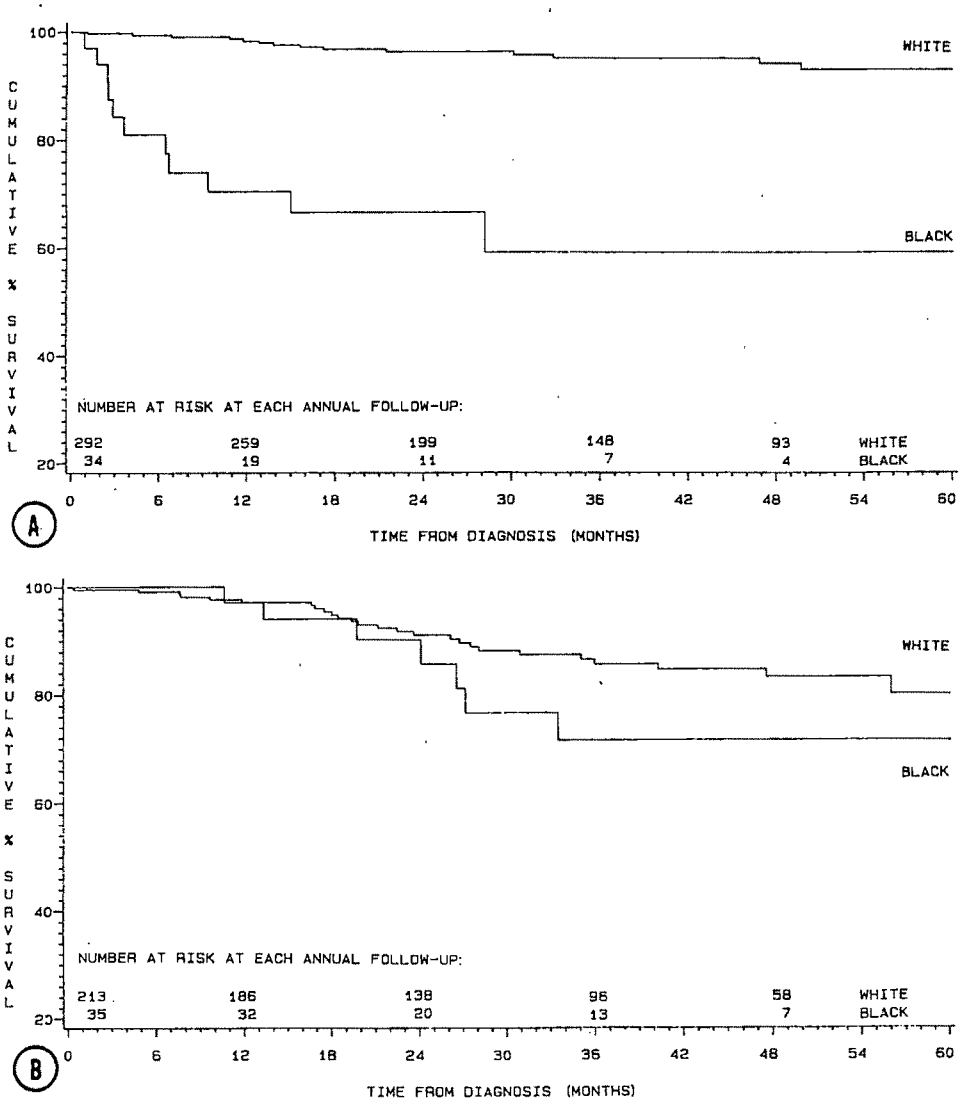

Fig. 3. A, Survival of women with endometrial cancer by race for patients who did not receive adjuvant radiation therapy. **B,** Survival of women with endometrial cancer by race for patients who received adjuvant radiation therapy.

characteristics. The estimated hazard rate ratio after adjustment for age at diagnosis, marital status, county of residence, histologic grade, cervical extension, and extrauterine involvement was 3.62, with 95% confidence limits of 2.15 and 6.12. Thus the estimated prognostic effect of race was not altered by the inclusion of histologic grade into the regression model. The inclusion of depth of myometrial invasion instead of histologic grade along with the demographic and tumor characteristics of model 1 also did not alter the prognostic effect of race.

To characterize further the racial difference in survival found in the multivariate analysis, the race-specific survival curves for deaths caused by endometrial cancer are depicted in Fig. 2, *A*, for women with favorable prognoses and in Fig. 2, *B*, for women with unfavorable prognoses. Among women with favorable disease, the product limit survival curve was significantly higher for whites compared with blacks (generalized Wilcoxon test: $\chi^2 = 3.95$, df = 1, $p = 0.047$). An even greater racial difference in survival was detected among the women with unfavorable prognoses (generalized Wilcoxon test: $\chi^2 = 30.7$, df = 1, $p < 0.001$).

Inclusion of treatment factors. The analysis was extended to include information on treatment and the previously mentioned demographic and tumor characteristics. The potential prognostic treatment factors considered were surgical treatment (1 = not done) and radiation treatment (1 = done).

Before reconstruction of the regression models, possible interactions between race and each of the treatment factors were estimated. Survival was better for

†((Observed deaths-expected deaths)/(woman-years of follow-up)) × 1000.
‡See Table II for definitions of favorable and unfavorable prognosis.

whites compared with blacks, regardless of whether surgery was performed. Among women who received surgery without adjuvant radiation therapy, whites had a significantly higher survival probability than did blacks (Fig. 3, *A*, generalized Wilcoxon test: $\chi^2 = 57.8$, df = 1, $p < 0.001$). There was no significant racial difference in survival among the women who received adjuvant radiation therapy (Fig. 3, *B*, generalized Wilcoxon test: $\chi^2 = 1.6$, df = 1, $p = 0.208$).

The estimated regression model that used the demographic, tumor, and treatment characteristics except for histologic grade indicated that race was a significant predictor of survival among women not receiving radiation treatment (estimated hazard rate ratio = 6.90, with 95% confidence limits of 3.41 and 14.0). Among women receiving radiation treatment, race was not a significant predictor of survival (estimated hazard rate ratio = 1.84, with 95% confidence limits of 0.72 and 4.75).

The estimated regression model that used the same demographic, tumor, and treatment characteristics, and histologic grade is presented as model 2 in Table IV. Again, race was a significant predictor of survival among women not receiving radiation treatment (estimated hazard rate ratio = 8.05, with 95% confidence limits of 3.73 and 17.4) but not among women receiving radiation treatment (estimated hazard rate ratio = 1.73, with 95% confidence limits of 0.60 and 4.98). Replacement of histologic grade by depth of myometrial invasion did not alter the prognostic effect of race, which indicated the absence of confounding by either histologic grade or depth of invasion.

Excess death rate analysis. The observed and expected number of deaths from all causes and the cor-

responding excess death rates from all causes during a 36-month follow-up period for women surviving at least 1 month are presented in Table V. For the entire study population, 61.9 more deaths were observed per 1000 woman-years of follow-up than would be expected in a population of Georgians with the same distribution of age, race, and sex.

When excess death rate analysis was performed separately for each racial group, the excess death rate for black women of 239.4/1000 woman-years was significantly greater ($p < 0.001$) than that of 40.3/1000 woman-years among white women. Stratification of the excess death rate by race and separate tumor characteristics revealed a significantly ($p < 0.005$) greater rate of excess deaths for black women with or without differentiated tumors, women with no cervical extension, and women with or without extrauterine involvement. The excess death rate for blacks also tended to be greater than that for whites among women with cervical extension; however this difference did not reach statistical significance ($p = 0.12$).

The effect of tumor characteristics on the racial difference in excess death rates was characterized further by the disease prognosis classification (favorable versus unfavorable). The excess death rates (per 1000 woman years) among women with favorable disease were 6.2 for whites and 82.4 for blacks. Among women with unfavorable prognoses, the excess death rates were 150.9 for whites and 476.6 for blacks. The estimated excess death rate for whites was significantly lower among women with favorable disease ($z = 2.24$, $p = 0.025$) and among women with unfavorable disease ($z = 3.65$, $p < 0.001$). The racial difference in excess death rates was significantly greater among the women with unfavorable prognoses compared with women with favorable disease (test for heterogeneity: $z = 2.61$, $p = 0.009$).

The racial difference in excess death rates of women with endometrial cancer by adjuvant radiation treatment indicated again that there was a greater racial difference in excess death rates for women who received no adjuvant radiation treatment compared with women who received adjuvant radiation treatment (test for homogeneity: $z = 2.16$, $p = 0.03$).

Comment

The most consistently reported prognostic factors for women with endometrial cancer are age,[14, 15] depth of myometrial invasion,[14-16] and histologic grade.[15, 16] In the present investigation, each of these variables was found to be a predictor of survival in both univariate and multivariate analyses. As noted elsewhere,[16] histologic grade is related to age, with a higher proportion of undifferentiated lesions in elderly women.

In addition to the established prognostic factors for endometrial cancer, the present work indicated that race was a statistically significant predictor of survival. The influence of race was strongest for women with undifferentiated malignancies and/or nonlocalized disease. Among women who did not receive radiation treatment, blacks had a worse survival experience than whites after adjustment for other demographic and tumor characteristics. In contrast, no racial difference in survival was observed among women who underwent radiation therapy.

There are several possible explanations for the present findings. First, it is possible that systematic errors in sample selection or data collection may have occurred. With regard to the sampling strategy, an attempt was made to identify all women with endometrial cancer from a large biracial metropolitan community. Although clinically occult neoplasms could have escaped detection, the small percentage (0.3%) of patients who were diagnosed only at autopsy implies that the incidence of clinically unrecognized endometrial cancer is low.

A greater potential loss of subjects from the present study was related to the absence of complete information on all variables of interest. Almost one third of the study population had missing data on either histologic grade or depth of myometrial invasion. To minimize the exclusion of subjects with missing data from the regression models, multivariate analyses were constructed with the inclusion of either histologic grade or myometrial invasion. Adjustment for the separate effects of these variables did not alter the prognostic significance of race. Since similar results were obtained regardless of which subjects were excluded, it does not appear that bias was introduced through missing information.

The findings of this investigation might have also been influenced by inaccuracies within the collected data. However, misdiagnoses are unlikely in the present context, since microscopic confirmation of disease was required for eligibility. The primary outcome of this study was death from endometrial cancer. It is possible that the assignments of causes of death differed systematically for white and black women with endometrial cancer. The excess death rate analysis, however, was based on a comparison of relative mortality rates and did not require specification of causes of deaths. Since the results of the excess death rate analysis were consistent with the other analyses, it is unlikely that the racial difference in survival was attributable to differential classification of causes of death. Although it might have been useful to analyze other outcomes, such as treatment failures or recurrence of disease, the registry does not collect information on these events.

Several additional characteristics of this investigation should be noted. First, the median lengths of follow-

up were relatively short: white women, 34.1 months and black women, 20.5 months. As a consequence, long-term prognosis could not be evaluated. Second, the type of available information on treatments was limited, and therefore the effects of factors such as the dose of radiation therapy could not be evaluated. Third, the collected data only pertained to treatments that were administered in the first 4 months after diagnosis.

Despite these methodologic constraints, the results of the present investigation indicated a strong racial difference in the survival of women with endometrial cancer. The magnitudes of racial differences in survival probabilities were substantial and therefore unlikely to be attributable to chance. The most reasonable explanations for the observed disparity in survival relate to racial differences in the clinical management of women with undifferentiated malignancies and/or nonlocalized disease. Among such women, whites had a greater frequency of surgery than blacks. The overall use of radiation therapy was also more common among whites than blacks with unfavorable grades and/or stages. Moreover, the racial difference in survival was greatly diminished among women who underwent radiation therapy.

The present findings emphasize the need for further research on factors that may influence the choice of therapy for women with endometrial cancer. In particular, subsequent investigations should include data on the presence of concurrent illnesses, patient noncompliance with recommended treatments, and complications of therapy. Until such data are collected, it is premature to speculate on whether black women with endometrial cancer receive optimal clinical management.

The authors express their appreciation to the staff of the Georgia Center for Cancer Statistics who collected, coded, edited, and processed these data, and to the hospitals and physicians who provided information on patients with endometrial cancer. Mr. Scott Clark helped perform the statistical analyses.

Endometrial adenocarcinoma estrogen receptor content: Association of clinicopathologic features with immunohistochemical analysis compared with standard biochemical methods

David G. Mutch, M.D., John T. Soper, M.D., Debra A. Budwit-Novotny, M.D., Edwin B. Cox, M.D. William T. Creasman, M.D., K. S. McCarty, Sr., Ph.D., and K. S. McCarty, Jr., M.D., Ph.D.

Durham, North Carolina

Endometrial adenocarcinomas from 96 patients were studied for their biochemical estrogen receptor content as well as immunohistochemical localization of estrogen receptor. A well-characterized specific monoclonal antihuman estrogen receptor antibody (H222 sp γ) as amplified by peroxidase/antiperoxidase techniques was used for immunohistologic localization. Immunohistochemical evaluation incorporated both the intensity and distribution of staining into a semiquantitative analysis (HSCORE). The total HSCORE was the sum of the relative contributions of the four histologic components: benign epithelium, malignant epithelium, stroma, and myometrium. These results were compared with clinicopathologic features of the tumors. Excellent sensitivity (91.5%) and specificity (93.1%) were observed for immunohistochemical analyses as compared with the biochemical analysis of estrogen receptor for these tissues. The cancer component HSCORE correlated better with grade than did the biochemical estrogen receptor determination. Correlation was also observed between surgical stage and estrogen receptor content. Decreasing biochemical estrogen receptor content predicted advanced surgical stage ($p = 0.0003$), as did the total HSCORE ($p = 0.003$); however, the HSCORE of the cancer component only did not correlate with advanced surgical stage ($p = 0.11$). Although immunohistochemical analyses predicted biologic differentiation better than did the biochemical technique, stage correlated better with biochemical estrogen receptor analysis and total HSCORE than did the cancer component HSCORE. The HSCORE of the cancer component may better predict biologic behavior and therefore identify cancers more likely to respond to hormonal therapy. (Am J Obstet Gynecol 1987;157:924-31.)

Key words: Estrogen receptor, monoclonal antibody, endometrial carcinoma

Hormonal manipulation is effective in the treatment of many neoplasms derived from steroid-dependent tissues. The ability of steroid receptor content to predict biologic behavior in patients with breast carcinoma has been well established.[1] The clinical value of steroid receptor analysis has not been as well established for endometrial carcinomas, although clinicopathologic associations with receptor content have been observed.[2, 3] Marked tissue heterogeneity seen in endometrial carcinoma specimens may confound interpretation of steroid receptor content derived from biochemical assays of whole tissue homogenates. Unlike nonneoplastic breast tissues, which contain only low levels of sex steroid receptor, uterine and endometrial tissues often contain appreciable amounts of receptor. The relative amount that the estrogen receptor content of myometrial, stromal, and benign glandular epithelial elements contribute to the total estrogen receptor of tissue homogenates of individual endometrial carcinoma specimens is not clear, but these benign elements could contribute significantly to measured receptor.[4, 5] In addition, endometrial carcinomas often show multiple patterns of differentiation and cell type within individual lesions, often within a single histologic section of that lesion.[5]

Concentrations of cytosolic estrogen and progesterone receptors from different regions of the normal uterus are not identical.[6] The current biochemical assays of estrogen receptor content cannot account for heterogeneity of tissue type and the contribution to the total estrogen receptor content of tumor tissue samples, because they are performed on whole tissue homoge-

nates. Homogenation obscures the source and proportion of cells in heterogeneous populations.

The desire to develop reliable histochemical assays for estrogen and progesterone receptors stems principally from considerations of the potential significance of heterogeneity of tissue type and heterogeneity of tumor receptor content, as well as the need for relatively large amounts of tissue for the usual biochemical steroid receptor assay. Previous attempts to evaluate receptor content with fluorescent-conjugated steroids or antisteroid hormone antibodies have not been successful.[7, 8] The recent development of specific monoclonal antibodies against human estrogen receptors offers the opportunity for specific localization of estrogen receptor within various tissue components.[9, 10] We compared clinical and pathologic associations of biochemical and immunohistochemical estrogen receptor assays of endometrial carcinomas to determine the significance of the estrogen receptor contribution of noncancerous components.

Material and methods

Ninety-six specimens from patients with endometrial adenocarcinoma treated at Duke University Medical Center from January 1, 1980, to December 31, 1983 were submitted for histopathologic examination and analysis of estrogen receptor content by both biochemical and immunohistochemical techniques. All patients were surgically managed and tissue was obtained from the hysterectomy specimen. None of the patients received preoperative radiation. In addition to preoperative staging according to the International Federation of Gynecologists and Obstetricians guidelines, all patients were retrospectively surgically staged. Surgical staging consisted of total abdominal hysterectomy, pelvic and periaortic selective lymphadenectomies, and pelvic washings. Retroperitoneal lymph nodes were sampled in patients with grades 2 and 3 lesions, as well as all grade 1 lesions with deep myometrial invasion detected at the time of surgery. Evaluation of myometrial invasion was made on the basis of intraoperative sectioning of the uterus. Patients with Stage I, grade 1 lesions and only superficial myometrial invasion underwent total abdominal hysterectomy, bilateral salpingo-oophorectomy, and pelvic cytologic examination.

Surgical stages were defined as follows: Stage I, disease confined to the uterus; Stage II, disease involving the cervix; Stage III, lymph node or pelvic metastases; and Stage IV, disease in upper abdomen or distant metastases. All grading of specimens was performed by three observers (K. S. M., Jr., D. B., and J. T. S.) on material submitted for estrogen receptor analyses.

Biochemical estrogen receptor analyses. Estrogen receptor content of the tissues was analyzed according to a modification of the methods described by Schrader et al.[11] Tissue was obtained immediately in the fresh state, washed in buffer (10 mmol/L Tris HCl, 5 mmol/L HEPES HCl, 1.5 mmol/L EDTA, 1.0 mmol/L thioglycerol, and 0.02% NaN_3, pH 7.4) at 4° C, quick frozen in liquid nitrogen, and maintained at −80° C in airtight liquid nitrogen capsules until assayed. The frozen tissue was pulverized in liquid nitrogen by a Spex freezer mill at 3/4 power with a stainless steel impeller for 15 seconds (five 3-second cycles). The tissue powder was homogenized at a sample:buffer volume of 1:6 at 4° C by a Polytron (setting 3) for 60 seconds (four 15-second cycles with 30-second cooling periods). Cytosol was prepared from the homogenate by centrifugation at 1000 × g for 10 minutes followed by 145,000 × g for 1 hour, both a 4° C. Endogenous unbound steroid was removed by 0.75% (w/v) Norit A in 0.0025% dextran. The supernatant protein content was analyzed by the method of Bradford[12] and adjusted to a protein content of 4 to 6 mg/ml. Sucrose density gradient analysis and multiconcentration dextran-coated charcoal analysis were performed as previously described.[13]

Immunohistochemical estrogen receptor analysis. Portions of the tissue specimens that had been fresh frozen in liquid nitrogen for biochemical assays were prepared as serial 4 to 6 μm cryostat sections mounted on poly-L-lysine–coated slides. The initial section was fixed in 3.7% formalin in 0.01 mmol/L phosphate buffered saline solution and stained with hematoxylin-eosin for tissue diagnosis and correlation with the presence of immunohistochemical staining. Histologic grade of the tumor was evaluated based on the cryostat section prepared for immunohistochemical receptor analyses (see below) with classification according to International Federation of Gynecologists and Obstetricians criteria. Assignment of tumor type and grade was confirmed by review of formalin-fixed, paraffin-embedded, hematoxylin-eosin–stained sections taken from the same specimens.

Monoclonal antibody H222 Sp γ developed against MCF-7 human breast cancer estrogen receptors by Dr. L. S. Miller of Abbott Laboratories was selected for this study. This monoclonal antibody has been shown to be specific for human estrogen receptors from human endometrium and human breast cancers by several criteria.[14] H222 Sp γ recognizes a stable and well-conserved determinant that is close to the steroid binding site. Peroxidase/antiperoxidase staining for immunohistochemical localization was performed as follows. Cryostat sections were placed in 3.7% formaldehyde–phosphate-buffered saline solution for 10 minutes. They were then transferred to a bath until formalin fixation had been completed for all sections in a given run. Slides were placed in cold absolute methanol at −15° to −20° C for 4 minutes, and then in cold acetone at −15° to −20° C for 1 minute. Afterward,

Table I. Stage versus grade

	Grade 1	*Grade 2*	*Grade 3*	*Total*
Stage I	29	30	6	65 (67.7%)
Stage II	4	1	4	9 (9.4%)
Stage III				
Nodes	6	2	5	13 (13.5%)
Pelvic metastases	1	4	2	7 (7.2%)
Stage IV		1	1	2 (2%)
Total	40 (41.6%)	38 (39.5%)	18 (18.7%)	

slides were washed in phosphate-buffered saline solution twice for 5 minutes each at ambient temperature. Sections were treated with 2% normal goat serum in phosphate-buffered saline solution for 15 minutes in a humidified chamber, to reduce the nonspecific binding of bridging antibody (see below). Sections were incubated with primary antibody (H222 Sp γ, 5 μg/ml; 33 pmol/ml in phosphate-buffered saline solution) for 30 minutes at ambient temperature. Negative control slides of adjacent cryostat sections from each of the same tissues were incubated with control antibody (normal nonimmunized rat serum in phosphate-buffered saline solution) in place of the primary antibody for 30 minutes. Control slides of estrogen receptor–rich MCF-7 human breast cancer cells were incubated with primary or control antibody. Slides were then washed in phosphate-buffered saline solution two times for 5 minutes each. Sections were incubated with bridging antibody (goat antirat immunoglobulin in phosphate-buffered saline solution) for 30 minutes. Slides were again washed in phosphate-buffered saline solution twice for 5 minutes each. Peroxidase-antiperoxidase complex (horseradish, peroxidase, and rat antihorseradish peroxidase in phosphate-buffered saline solution) was applied to the sections for 30 minutes, after which slides were washed in phosphate-buffered saline solution twice for 5 minutes each. The slides were then flooded with 8 mg diaminobenzidine/16 ml hydrogen peroxide in phosphate-buffered saline solution for 6 minutes in the dark. The solution had been prepared under minimal light and was used within 30 minutes. Sections were rinsed in gently running tap water for 5 minutes and dehydrated in serial alcohols to xylene; coverglasses were applied with Permount without counterstaining.

In the presence of hydrogen peroxide, the tissue-bound peroxidase converts the diaminobenzidine chromagen to an insoluble, brown reaction product that can be seen with a light microscope. Thus the minute quantity of estrogen receptor/monoclonal antibody complex is amplified through the use of the bridging antibody, peroxidase-antiperoxidase complex, and enzyme reaction products.

Scoring of assays. Biochemical assays were summarized as femtomoles of specific estrogen binding per milligram of tissue protein. The immunohistochemical localization was scored in a semiquantitative fashion incorporating both the intensity and distribution of specific staining. Evaluations were recorded for each observed tissue component (i.e., myometrium, stroma, benign epithelium, and malignant epithelium) as the percentage of cells in each of four intensity categories. The intensity of specific staining was characterized as not present (0), weak but detectable above control (1+), distinct (2+), and very strong (3+). For each observed tissue component, a summary value (HSCORE) was calculated that consisted of a sum of the percentages of positively stained cells multiplied by a weighted intensity of staining:

$$\text{HSCORE} = \sum_{i=0} P_i(i + 1)$$

where P_i is the percentage of stained cells in each intensity category and i is the intensity for i = 1,2,3. A total HSCORE for the tissue section was derived as the sum of the component HSCORE weighted by the fraction of each component observed in the tissue section, as follows:

Total HSCORE =
[(Cancer HSCORE × percent cancer)/100]
+ [(stromal HSCORE × percent stroma)/100]
+ [(myometrial HSCORE × percent myometrium)/100] +
[(benign epithelium HSCORE × percent benign epithelium)/100

Biochemical assays were compared with the total HSCORE as well as the individual component HSCORE values.

Sections were evaluated independently by two observers and were further reviewed by the initial observer. Intraobserver ($r = 0.98$, $p = 0.00001$) and interobserver differences for total HSCORE were resolved by consensus evaluation ($r = 0.99$, $p = 0.00001$ for primary observer versus consensus total HSCOREs).

Data management and analysis. Biochemical assay values and immunohistochemical assay values were coded separately in a blinded fashion and maintained

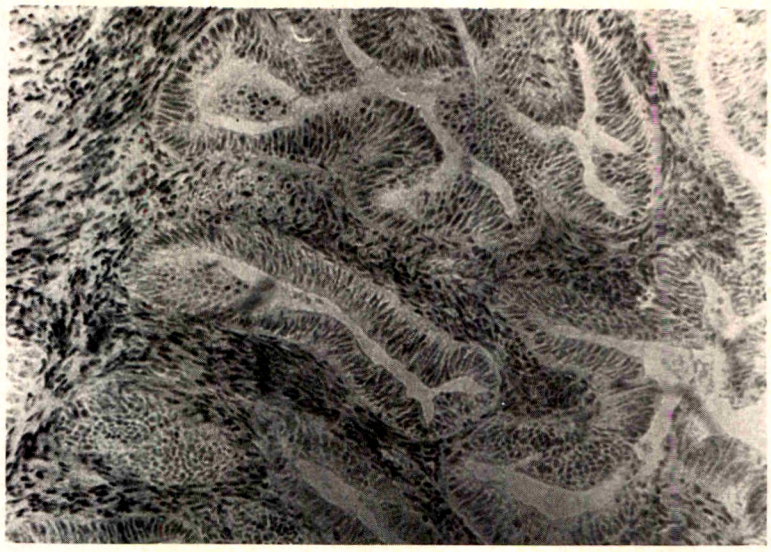

Fig. 1. Very well-differentiated adenocarcinoma of the endometrium shows marked myometrial staining for estrogen receptor. Nuclear staining is almost exclusively present.

as independent files in the Time-Oriented Record for Oncology system of the Duke Cancer Center database until the completion of each phase of the study. Record identification numbers were used to match samples for the analysis. Accuracies, sensitivities, specificities, and predictive values were determined. The correlations were analyzed with the Spearman rank test for ordinal data (stage, grade) or the Pearson correlation for continuous data (biochemical estrogen receptor, HSCORE). Significance of two-way tables was determined by χ^2 test or Fisher's exact test as appropriate. Differences in assay values between groups based on stage and grade were tested for significance by the Mann-Whitney U test. Distributions were plotted as the cumulative proportion of observations having a value less than or equal to the corresponding value on the abscissa (the cumulative distribution function).

Results

Ninety-six patients were evaluated completely. Forty patients (41.6%) had grade 1, 38 (39.5%) had grade 2, and 18 (18.8%) had grade 3 lesions. Sixty-five patients (67.7%) had surgical Stage I disease, nine (9.4%) had surgical Stage II disease, 13 (13.5%) had Stage III disease with pelvic metastases, seven (7.2%) had Stage III disease with lymph node metastasis, and two (2.0%) had Stage IV disease (Table I). Increasing surgical stage correlated with worsening tumor grade ($p = 0.016$, Spearman).

Immunohistochemical estrogen receptor analysis with monoclonal antibody H222 Sp γ characteristically showed nuclear localization of specific staining above control values in all tissue components. Critically, the amount of staining in the cancer component often diverged from that in the stromal or myometrial components (Figs. 1 and 2). Fig. 1 shows marked myometrial staining with only a small amount of epithelial localization. In contrast, Fig. 2 shows marked staining of the malignant epithelial component with little localization in surrounding myometrium or stroma. Fig. 2 also demonstrates a heterogeneous pattern of staining within the malignant epithelial tissue itself. Among stromal and myometrial elements, however, staining tended to be more homogeneous, and in normal epithelium staining was usually uniform.

The total HSCORE correlated strongly with the biochemical estrogen receptor assay. Threshold positivity (≥10 fmol/mg protein) was predicted by the total HSCORE (≥75) with a sensitivity of 92% and specificity of 93%. Total HSCORE correlated more closely with estrogen receptor ($r = 0.68$) than with the malignant epithelial ($r = 0.65$) and stromal or myometrial ($r = 0.35$) components.

When lesions were categorized by histologic grade, estrogen receptor localization by the immunohistochemical technique in the cancer component only was virtually absent in the majority (88% negative) of poorly differentiated (grade 3) cancers; it was present in most (92%) of the well-differentiated tumors (grade 1); values were intermediate in the group with intermediate differentiation (grade 2). In the latter group there appeared to be two, and possibly three, distinct populations of lesions identified by the HSCORE of the cancer component: negative, low positive, and strongly positive (Fig. 3).

Biochemical analysis of estrogen receptor content did not distinguish among populations of differing histologic grade as well as the HSCORE of malignant epi-

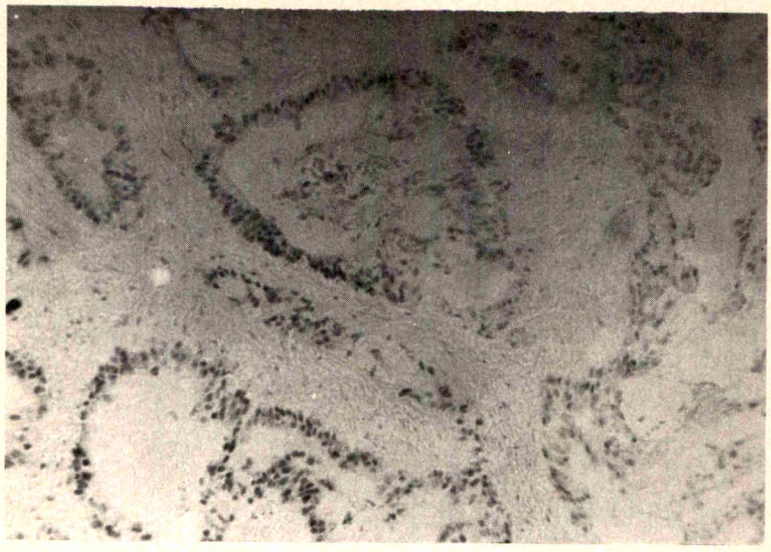

Fig. 2. Moderately differentiated adenocarcinoma of the endometrium. There is a weak myometrial staining relative to cancer component staining and heterogeneity of staining within the cancer component.

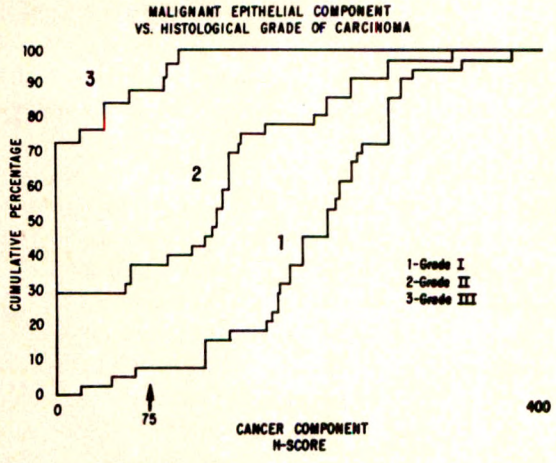

Fig. 3. Cumulative distribution function of cancer component HSCORE versus grade. *Arrow* denotes threshold value of 75. Of the grade 1 lesions, 8% are estrogen receptor–negative; 88% of grade 3 lesions are estrogen receptor–negative. Increments are from 40 to a total score of 400. 1 versus 2, $p = 0.000027$; 1 versus 3, $p < 0.00001$; 2 versus 3, $p < 0.00005$.

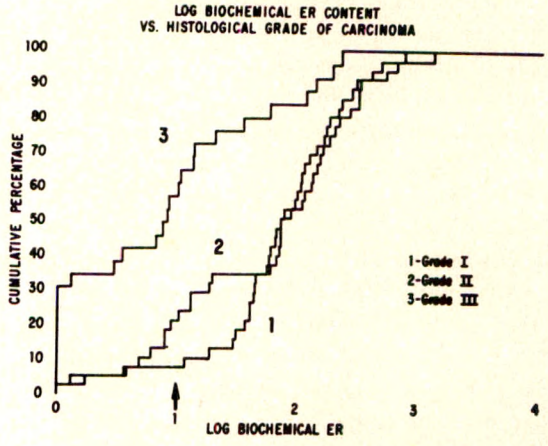

Fig. 4. Cumulative distribution function of log biochemical estrogen receptor *(ER)* versus grade. *Arrow* denotes threshold value of 10 fmol/mg protein. Of the grade 1 lesions, 8% are estrogen receptor–negative; 57% of grade 3 lesions are estrogen receptor–negative. 1 versus 2, $p = 0.18$; 1 versus 3, $p = 0.00002$; 2 versus 3, $p = 0.0004$.

thelial component did. The distribution of the biochemical estrogen receptor assay among grades 1 and 2 was indistinguishable, but these distributions were clearly distinct from that in grade 3 lesions (Fig. 4). The total HSCORE distribution was intermediate between the biochemical estrogen receptor and the cancer component HSCORE in discriminating among histologic grade. The cumulative distribution function demonstrates clear discrimination between each of the three grades (Fig. 5). However, the degree of separation was not as distinct as with the cancer component HSCOREs alone. There was a relatively equal estrogen receptor staining contribution of the stroma and myometrial elements in each histologic grade of the cancer.

Cancer component HSCOREs were not significantly associated with clinical or surgical stage (Fig. 6) as determined by comparison of intrauterine versus extrauterine disease ($p = 0.11$, Mann-Whitney). The distribution of total HSCORE between groups of Stages I

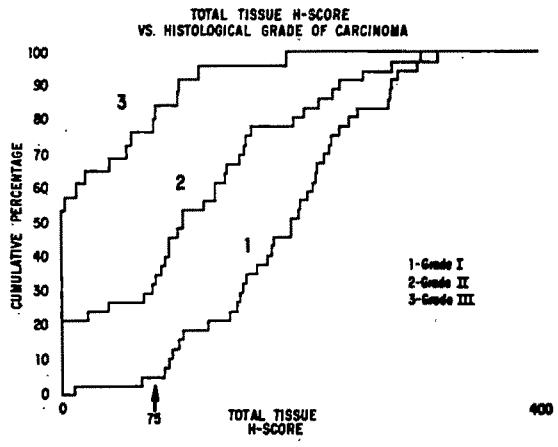

Fig. 5. Cumulative distribution function of total tissue HSCORE versus grade. *Arrow* denotes threshold value of 75. Of the grade 1 lesions, 5% are estrogen receptor–negative. Increments are from 40 to a total score of 400. 1 versus 2, p = 0.0008; 2 versus 3, <0.00001; 2 versus 3, p = 0.00006.

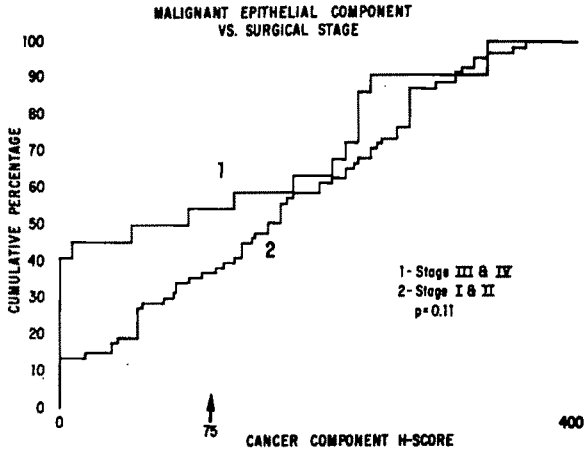

Fig. 6. Cumulative distribution function of malignant component only against surgical stage. *Arrow* denotes threshold of 75. Thirty-seven percent of Stages I and II lesions are estrogen receptor–negative, versus 54% of Stages III and IV.

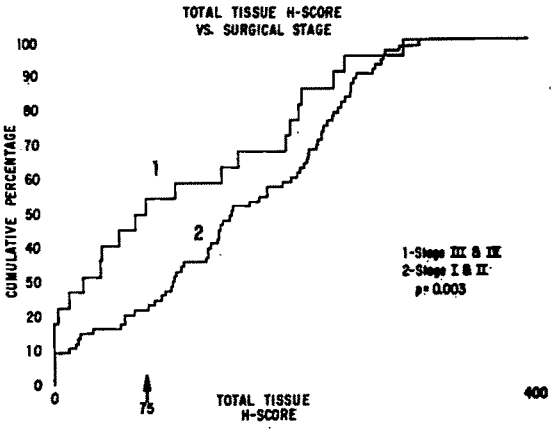

Fig. 7. Cumulative distribution function of total HSCORE versus surgical stage. *Arrow* denotes threshold value of 75. Twenty-two percent of Stages I and II lesions are estrogen receptor–negative, versus 54% of Stages III and IV.

and II versus groups of Stages III and IV were significant (p = 0.03, Mann-Whitney; Fig. 7). Distribution of the biochemical estrogen receptor constant was significantly different between stage breakdown (p = 0.003, Mann-Whitney; Fig. 8). There was no difference in the percentages of benign and malignant components present by stage, nor was there any difference in early versus advanced stage cancer.

Comment

In contrast to breast cancer, in which the surrounding mesenchymal elements and benign epithelium contain low or nonmeasurable quantities of sex steroid receptor, the mesenchymal elements in endometrial carcinomas may contain significant quantities. As a consequence, analysis of steroid receptor content of endometrial carcinomas based on biochemical assays of total tissue homogenate may be unreliable for predicting the biologic behavior of the neoplasm. Benign epithelial, stromal, and myometrial elements contain significant amounts of steroid receptor and may contribute quantifiable levels of receptor to the levels measured in individual endometrial carcinoma specimens. Conventional histologic methods can exclude specimens in which significant proportions of the tissue are benign, but cannot provide information about the relative contributions of these various tissue components to the total biochemical estrogen receptor once the tissue is homogenized. For these reasons, a reliable histologic technique for localizing and quantifying sex steroid re-

ceptors is particularly desirable in studying the steroid receptor content of endometrial carcinomas.

The present immunohistochemical technique with H222 Sp γ monoclonal antibody demonstrates good sensitivity and specificity for total HSCORE when compared with standard biochemical estrogen receptor measurements. The total HSCORE discriminated histologic grade with more effective separation of subgroups than was possible with the biochemical estrogen receptor analysis. This separation was even greater when the estrogen receptor contributions of the stromal, myometrial, and benign components were excluded and the malignant epithelial HSCORE was compared with grade (Fig. 3). This cumulative distribution function also demonstrates that grade 2 lesions may be subgrouped into three categories by estrogen receptor content of the malignant component: One subgroup contained little or no estrogen receptor (component HSCORE <75); an intermediate subgroup had a low positive estrogen receptor component HSCORE (75 to 200); and the third subset had a strongly positive component HSCORE (>200). Histologic grading alone could not discriminate any of these subgroups. Therefore, immunohistochemical estrogen receptor evaluation of the cancer component may help determine biologic differentiation and predict tumor behavior better than standard biochemical assays for estrogen receptor that involve whole tissue homogenates, in which discrimination is confounded by the contribution to total estrogen receptor by stroma and myometrium. This concept is underscored when one appreciates that the estrogen receptor content of the myometrium/stroma is often discordant with that of the malignant epithelial component (Fig. 2).

A significant amount of nonepithelial tissue may enter into the biochemical evaluation of estrogen receptor content, thus potentially altering the estimate of biologically important estrogen receptor in the cancerous tissue.[5, 6] In this patient population, both estrogen receptor contribution by percent of HSCORE and percent "benign" contribution by volume of tissue compared with grade and stage were similar between the categories (Fig. 6). Further observations are required to assess the significance of stromal/myometrial estrogen receptor content in predicting the clinical behavior of endometrial carcinoma. We have previously reported a strong prognostic effect of steroid receptor content for predicting disease-free survival in patients with endometrial carcinoma after therapy.[13] Stage correlated well with biochemical estrogen receptor analysis and with the total HSCORE, but did not correlate with HSCORE of the cancer component. Because histologic grade appears to be a biologically relevant factor, and because the component HSCORE of malignant epithelial elements correlated most strongly with grade, one would predict that the cancer component HSCORE would predict stage better than the biochemical estrogen receptor or total HSCORE. In fact, the opposite was observed (Figs. 6 to 8), with biochemical estrogen receptor and total HSCORE relating to stage better than the cancer component HSCORE ($p = 0.003$ and $p = 0.03$ versus 0.11). To evaluate this observation further, the contribution of benign components (stromal, myometrium, and benign epithelium) was analyzed by stage and grade. No differences were noted among groups.

At least two factors may contribute to stage: duration of disease and biologic differentiation of a neoplasm. Histologic differentiation and estrogen receptor content are indirect measures of biologic behavior, but there are likely other aspects not evaluated by these that also contribute to the ability for endometrial carcinoma to metastasize. The duration of disease from its time of inception cannot be determined, but the reverse trend with stage of HSCORE is consistent with the concept that receptor-positive epithelial lesions are slower growing.

A critical observation is the heterogeneity observed between components of endometrial carcinoma. Malignant tissue tends to respond to its environment in an asynchronous fashion (Figs. 1 and 2). In contrast, normal endometrial tissue components tend to respond in synchrony to their hormonal environment.

The immunohistochemical technique described allows the simultaneous determination of the contribution of individual components to the measured estrogen receptor value and the identification of subgroups within populations of lesions and similar histologic differentiation. Data indicate that the estrogen receptor content of these components may be divergent and, further, that the HSCORE of the malignant epithelium does not simply reflect data already provided by stage categorization. Immunohistochemical analysis may therefore represent an important independent variable reflecting tumor differentiation at a biochemical level. Not only does this analysis allow reliable and reproducible quantitation of the estrogen receptor content of the malignant epithelium, it may also allow better evaluation of the interactions of stroma, myometrium, and malignant epithelium, thus permitting the study of malignant tissue response to the hormonal environment in relation to benign tissue response. Finally, this technique allows evaluation of the estrogen receptor content in the cancer component only and therefore may predict biologic behavior better than techniques that involve whole tissue homogenates.

We thank Abbott Laboratories and Dr. Larry Miller and John Konrath for the kind gift of the H222 γ

antibody. We also thank Ms. Julie Flowers for her technical advice and Ms. Donna Silva for her assistance with the preparation of the manuscript.

Colposcopic evaluation of abnormal Papanicolaou smears in pregnancy

J. L. Benedet, M.D., P. A. Selke, M.D., and K. G. Nickerson, M.D.
Vancouver, British Columbia, Canada

Colposcopy was used to examine 401 pregnant patients with cytologic or clinical abnormalities of the cervix to determine if routine biopsy could be safely omitted except where the colposcopic impression was one of possible invasive carcinoma. A comparison of the antepartum colposcopic impressions with the postpartum histologic diagnosis revealed agreement to within one degree in 87% of patients, with 3% of patients showing a more advanced lesion than that anticipated. Only 2% of patients showed a progression of cytologic abnormalities at postpartum examination; 39% showed marked improvement. Four of nine patients with invasive carcinoma were diagnosed at antepartum colposcopy, with an additional two patients recognized as having invasive cancer at the postpartum colposcopic examination. The omission of routine biopsy is less than ideal if only one antepartum colposcopy is performed, since a considerable period of time may elapse before the patient is seen again postpartum. Those situations in which it may be omitted, together with guidelines for the management of pregnant patients with abnormal cervical ctyologic findings, are presented. (AM J OBSTET GYNECOL 1987;157:932-7.)

Key words: Abnormal Papanicolaou smears, pregnancy, colposcopic evaluation

An abnormal Papanicolaou smear during pregnancy is not uncommon given that the peak incidence[1] for preclinical cervical neoplasia is found in women in their third decade, which is also the time of maximum childbearing activity. Fortunately, few patients who have abnormal Papanicolaou smears during pregnancy are found to have invasive cervical carcinoma. Nevertheless, the occurrence of an abnormal cervical smear during pregnancy produces considerable patient anxiety regarding its significance and the effects that this might have on her pregnancy and fetus.

During the past decade, colposcopy has replaced cervical conization as the method of choice for the evaluation of patients noted to have an abnormal Papanicolaou smear during pregnancy. Although cone biopsy is an excellent method of histologic evaluation of abnormal cervical cytologic findings, the performance of this procedure in pregnancy has produced some difficulties. The physiologic changes that occur with pregnancy, namely, eversion of the squamocolumnar junction, together with increased vascularity and softening of the cervix, often make for greater technical difficulty. In addition, an increased risk of postoperative hemorrhage, premature onset of labor, cervical incompetence, and cervical dystocia are potential complications faced by the patient undergoing cone biopsy while pregnant. These risks can be eliminated by the use of colposcopy. Several publications[2-5] have attested to its safety and reliability. Although the need for colposcopy in the pregnant patient with an abnormal cervical smear is widely accepted, there is a lack of uniformity regarding the investigative protocols that should be used. In particular, more recent reports[2, 5, 6] have suggested that although the risk of significant hemorrhage after colposcopic biopsy is low, biopsies can be omitted if microinvasion or invasive carcinoma is not suspected on the basis of a lesion's colposcopic appearance.

In 1977, we reported[3] our preliminary experience with colposcopy during pregnancy in which all patients had routine biopsy and demonstrated good correlation between the colposcopic impression and the accompanying histologic findings. These results,[3] together with other reports[2, 5-7] that suggested that histologic verification should perhaps be limited to those lesions with features suggestive of invasive carcinoma, led us to modify our investigative protocol along these lines.

This study reports our experience with this approach in which we relied primarily on the colposcopic appearance and avoided routine biopsy in all patients. Biopsy specimens were taken in patients who had lesions that suggested possible invasive carcinoma or in situations in which the appearance was sufficiently nonspecific to make interpretation difficult. Wedge or cone biopsies were subsequently recommended in patients in whom the colposcopic evaluation was equivocal for

microinvasive disease. This experience was analyzed to see if these concepts could be supported and if further modifications of these guidelines could be made.

Material and methods

Between Jan. 1, 1977 and Dec. 31, 1985, 401 pregnant patients with clinical and/or cytologic abnormalities of the cervix were referred to the Vancouver General Hospital Colposcopy Clinic. At that time, their presenting cytologic findings were reviewed, and colposcopy was performed with the use of routine techniques. Colposcopically directed biopsy specimens were taken only if the lesions seen suggested possible microinvasive or invasive carcinoma. All patients were seen by the authors or fellows under their supervision. Endocervical curettage was not performed, but all patients were assessed regarding whether the transformation zone could be completely outlined, the squamocolumnar junction visualized in its entirety, and all margins of any lesions seen. If these criteria were met and correlation was obtained between the colposcopic and cytologic findings, the examination was classified as satisfactory. If these criteria were not met, the patient was deemed to have an unsatisfactory examination, and further investigation in the form of a wedge or cone biopsy was recommended if the cytologic examination showed suspicious or malignant cells. If wedge biopsy or cervical conization was performed, it was recommended that this be done if possible during the early second trimester.

Patients in whom invasive carcinoma was not apparent by colposcopy were not subjected to further investigation during pregnancy and were advised to return 6 weeks postpartum for repeat cytologic and colposcopic examination. At that time, colposcopically directed biopsy specimens were taken of the most significant area of any lesions seen. The patients referred to the Colposcopy Clinic were seen only for consultation. Further investigation and management of these patients were determined by their physicians.

Patients in whom a diagnosis of occult invasive carcinoma was established during pregnancy were treated by radical hysterectomy and pelvic lymphadenectomy at the earliest opportunity, with consideration given to potential fetal viability in accordance with the wishes of the patient and her spouse. If microinvasive carcinoma was diagnosed or suspected, cone or wedge biopsies were performed, and if the diagnosis was confirmed, a recommendation was made to undergo simple hysterectomy on completion of the pregnancy.

Additional histopathologic findings were available for 106 patients who went on to hysterectomy or cone biopsy after pregnancy, thereby allowing for a comparison of the final pathologic diagnosis with the colposcopic evaluation.

Table I. Age and parity

Age (yr)	*No. of patients*	*Parity*	*No. of patients*
16-20	51	0	207
21-25	116	1	139
26-30	151	2	42
31-35	69	3	8
≥36	14	≥4	5
Total	401		401

Sixty-seven patients had colposcopically directed biopsies while pregnant; two patients also underwent wedge biopsy, and one patient had a cone biopsy performed.

Results

The age and parity of the patients under review are presented in Table I. Three hundred forty-six patients (86%) were para 1 or less, and 318 patients (79%) were 30 years of age or younger, indicating that the population studied consisted essentially of young women who were either nulliparous or of low parity. Indeed, 42% of patients were under 26 years of age, an age when one would not normally expect to see invasive cervical neoplasia. The youngest and oldest patients examined were 16 and 41 years old, respectively.

Table II compares the initial colposcopic impression with the patient's presenting cytologic findings for the 401 patients. Patients with Class I negative cytologic findings were women referred because of a clinically suspicious cervix or persons recently treated for cervical intraepithelial neoplasia whose management was not completed. One hundred eight-six patients had suspicious (Class III) or malignant cells (Class IV) noted on their Papanicolaou smears that were suggestive of carcinoma in situ or early invasive disease. In an additional 105 patients, cells compatible with severe dysplasia or carcinoma in situ (cervical intraepithelial neoplasia III) were reported.

None of the patients who had Class IV cytologic findings had lesions whose features suggested invasive carcinoma. All these patients were thought to have either severe dysplasia or carcinoma in situ.

Sixty-seven patients (17%) had a colposcopically directed biopsy at the time of this initial assessment. In four patients, invasive carcinoma was diagnosed, and 45 of the remaining 63 patients were found to have cervical intraepithelial neoplasia III.

Two hundred twenty-three patients had postpartum colposcopy and biopsy, which allowed for a direct assessment of our ability to predict the underlying histology. These results are noted in Table III. In 87% of patients, the colposcopic impression and the histologic appearance were within one degree of severity. In 24

patients (11%), the histologic diagnosis was less severe than that anticipated by the colposcopic impression, and in five patients (2%), a more advanced lesion was found on biopsy examination than what was predicted.

A similar analysis was done after review of the histologic findings of the 106 patients who had additional tissue specimens for evaluation either from conization or hysterectomy. This comparison is presented in Table IV and shows that once again the predictive ability was similar to that noted in Table III and the tendency of colposcopy to overcall the lesser forms of cervical intraepithelial neoplasia. The only notable difference is with the number diagnosed with invasive cancer. Five of the nine patients with invasive cancer shown in Table IV were diagnosed at subsequent postpartum investigation. Two patients had colposcopic features that suggested invasive carcinoma, and this was confirmed by directed biopsy in one patient. In the other patient, the postpartum biopsy examination did show carcinoma in situ, which was similar to the antepartum diagnosis, but now the lesion was not visualized completely, and its appearance was suggestive of invasive carcinoma; thus a diagnostic cone was recommended in cases in which an occult cancer was detected. Two patients had postpartum conizations, one without further colposcopic assessment and in another instance a cesarean-hysterectomy was performed because of a placenta accreta. All three of these women had occult in-

Total	348	129	41	35	52	82	9

vasive carcinomas and represent patients in whom the diagnosis of malignancy was not made or anticipated colposcopically.

In reviewing the patients' presenting cytologic findings with histologic specimens, which were obtained either colposcopically or at the time of conization or hysterectomy, it was noted that 73% of patients had cytologic findings predictive of the underlying disease. In 18% of patients, the histologic findings were less advanced than had been anticipated, with the remaining 9% of patients showing a histologically more advanced lesion than had been predicted by the cervical cytology report.

Table V compares the results of the antepartum and postpartum cytologic examination in 348 patients in whom this information was available. In 203 patients (58%), the antepartum and postpartum cytologic findings were similar; however, 134 patients (39%) exhibited a marked improvement in the degree of cytologic abnormality during the postpartum period. In contrast, only 11 patients (2%) had deterioration in their cytologic atypicality during pregnancy.

Table VI. Current status of 401 patients

Status	*No. of patients*
Postpartum colposcopy and biopsy	223
Cytologic follow-up only	98
Cone biopsy or hysterectomy	30
Cryotherapy	5
Undelivered	32
Lost to follow-up	13
Total	401

The current status of the 401 patients under review for this study is presented in Table VI. In 30 patients, the physicians elected to proceed directly to conization or hysterectomy postpartum without further cytologic or colposcopic investigation. In addition, 76 patients also had a hysterectomy or conization after postpartum

colposcopy and biopsy. Thirty-two patients were undelivered or less than 6 weeks' postpartum at the time of this evaluation, and in 13 patients, no further follow-up records could be obtained. Further management of the remaining 352 patients (88%) is also listed in Table VI.

A summary of the clinical findings in those patients with invasive carcinoma in this series is shown in Table VII. Five of the nine patients were older than age of 30 years, with a mean age of 32 years. Only 83 patients were in this age group. These five patients represent 6% of the 83 persons over 30 years old. In contrast, only four (1.3%) of 318 patients who were 30 years of age or less had invasive carcinoma. Furthermore, 58, or 70% of the 83 patients over the age of 30 years, had suspicious Class III or malignant Class IV cytologic findings on presentation. Of the 318 patients under the age of 30 years, 110, or 35%, had suspicious or malignant cytologic findings. Not only were patients 30 years of age or older twice as likely to have Class III or IV smears, but they were also approximately five times more likely to have invasive carcinoma.

All patients who underwent colposcopically directed biopsies during pregnancy did so without hemorrhagic complications. Premature labor or pregnancy loss did not occur in any patient.

Comment

The results of this study confirm that invasive cervical carcinoma is uncommon in pregnancy,[8] particularly in a heavily screened population such as ours. Nonetheless, whether such a lesion is present is the critical question that one must ask when confronted with a pregnant patient with abnormal cervical cytologic findings. Delay in the diagnosis of an early invasive carcinoma may result in a potentially curable lesion that progresses over the course of the pregnancy to the point where a successful outcome is no longer possible.

Analysis of the study data revealed that a proportionately larger number of patients over the age of 30 years had invasive cancer than those younger. Similarly, this older age group was also much more likely to have suspicious or malignant-appearing cells on their cervical smears than were younger patients. Thus the combination of age 30 years or more with a Class III or IV Papanicolaou smear should alert the physician that one is dealing with a particularly high-risk person who should probably have routine biopsy, even if the colposcopic appearance suggests only carcinoma in situ or a lesser lesion. The results of this and previous studies have shown that the risk of hemorrhage from a colposcopically directed biopsy is extremely low.

Routine biopsy need not be performed in all patients but to rely solely on the colposcopic appearance of the lesion presupposes that a lesion will have sufficient characteristics to permit its identification as such and that the colposcopist possesses the requisite expertise to allow for this recognition. In the current series, five patients with invasive carcinoma were not diagnosed until the postpartum period. In two patients, the colposcopic appearance postpartum was such as to suggest the diagnosis. Two patients did not have postpartum colposcopy, and in one patient the postpartum colposcopic impression and biopsy once again showed carcinoma in situ. This patient went on to have a simple abdominal hysterectomy at which time the diagnosis was made. It is possible that some of these lesions may have progressed from an intraepithelial to an invasive carcinoma over the course of the pregnancy, particularly since all were small-volume tumors. It is also possible, however, that in some of these patients an early invasive carcinoma was present at the outset and went

unrecognized at the time of the antepartum colposcopic assessment. Had routine biopsy been done, it may have had the advantage of alerting the physician to the need for further tissue investigation and on occasion may have shown an unexpected invasive carcinoma. All the patients who were diagnosed in the postpartum period had only one antepartum colposcopic examination early in the pregnancy. If further colposcopic examinations in these patients had been performed during the course of the pregnancy and if changes in the lesions were present, they may have been noted and the diagnosis made earlier.

In general, if an invasive carcinoma is present but not diagnosed at colposcopic examination, this is usually attributed to inexperience or colposcopist error. Sugimori et al.,[9] reporting on the colposcopic findings in microinvasive carcinoma of the cervix, reported that 7% of such patients had no colposcopic abnormalities suggesting neoplasia. Other reports[10-12] have also suggested that some lesions may not have features sufficiently atypical to permit easy recognition as early invasive carcinomas. Physicians are reluctant to report cases in which invasive carcinomas were not recognized at colposcopy for fear that the problem of nonrecognition would be attributed to the physician whereas it may be the technique that is at fault. If persons performing colposcopy adhere to established investigative protocols, colposcopist-related errors will be minimal.

Our experience to date with patients who have abnormal cervical cytologic findings during pregnancy leads us to believe that these are a special category of persons requiring specific management guidelines. This experience has led us to adopt the following guidelines: (1) All lesions with features suggestive of invasive carcinoma or carcinoma in situ should undergo biopsy examination at the initial visit, and if lesser pathologic findings are noted, repeat colposcopy and biopsy are performed in 4 weeks. (2) All patients 30 years of age or older with Class III or IV cervical cytologic findings are to have directed biopsies, even if the lesion seen is suggestive of a lesser disease than carcinoma in situ. (3) Patients should be seen as early as possible during pregnancy and then for 2 to 3 additional visits over the course of the pregnancy, depending on the gestational age of the patient. (4) Patients with suspicious or malignant cytologic findings (Class III or IV) who have an unsatisfactory colposcopic examination should be examined under anesthesia with colposcopy, and at that time a decision should be made regarding the need for wedge biopsy or cervical conization. (5) All patients should be seen 6 to 8 weeks' postpartum for repeat cytology, colposcopy, and biopsy. These guidelines are summarized in Fig. 1.

Although the vast majority of these patients will not have cancer, particularly the young patient with mild cytologic and colposcopic abnormalities and thus will not benefit from routine biopsy, its omission is less than ideal, since there is little doubt that colposcopically directed biopsy during pregnancy can be performed easily with minimal risk and complications.

Acute effects of exercise on plasma catecholamines in sedentary and athletic women with normal and abnormal menses

NeeOo W. Chin, M.D., Frank E. Chang, M.D., William G. Dodds, M.D., Moon H. Kim, M.D., and William B. Malarkey, M.D.
Columbus, Ohio

Norepinephrine plays a role in the regulation of luteinizing hormone secretion and may therefore be involved in the etiology of exercise-induced menstrual dysfunction. This study evaluated both intraexercise and postexercise responses of epinephrine, norepinephrine, and dopamine in sedentary women and women runners with normal and abnormal menstruation. Five eumenorrheic nonrunners and five eumenorrheic, four oligomenorrheic, and five amenorrheic runners were evaluated on 2 consecutive days. On day 1, the women cycled on a bicycle ergometer against an increasing work load until exhaustion, and on day 2, the women underwent a submaximal exercise regimen. Serial blood draws were taken at specified time intervals during intraexercise and postexercise periods on both days. The data collected during exercise for all groups showed that epinephrine and norepinephrine had a sixfold to sevenfold rise on day 1 and had a threefold rise on day 2. Dopamine increased twofold during both exercise protocols. On day 1 norepinephrine displayed a significantly higher percentage change from baseline to peak levels for oligomenorrheic and amenorrheic runners than for eumenorrheic runners and sedentary women. This latter finding is consistent with the hypothesis that periodic marked elevations in norepinephrine levels during maximal exercise may interfere with pulsatile luteinizing hormone release and hence may play a role in the occurrence of menstrual dysfunction in women runners. (Am J Obstet Gynecol 1987;157:938-44.)

Key words: Catecholamines, luteinizing hormone, women runners

Menstrual dysfunction has been found to occur in some female runners after the onset of training. A variety of hormonal alterations have been implicated as contributing to the dysfunction. Gonadotropin,[1] prolactin,[2] endorphin,[3] and catecholamine[4] levels have been found altered after the onset of regular or vigorous exercise. Studies in women athletes have shown cathecholamine rises after exercise in relation to increasing activity levels similar to men, but none have formally addressed the association between elevated catecholamine levels and exercise-related menstrual disturbance.

During strenuous exercise norepinephrine and epinephrine may attain levels that are similar to those obtained during norepinephrine and epinephrine infusions, which can produce hemodynamic and metabolic changes.[5] Recent works have implicated norepinephrine[6] in altering the pulsatility of luteinizing hormone release, which is critical for normal cyclic ovulatory function. This study examines the influences of maximal and submaximal exercise regimens on catecholamine secretion in sedentary women and women runners with and without menstrual dysfunction.

Material and methods

Subjects. Nineteen women (mean age 25.4 years, range 19 to 35 years) who gave informed consent were admitted to the Clinical Research Center at the Ohio State University Hospitals on two consecutive afternoons. This group of women had previously been involved with a study evaluating growth hormone and prolactin levels.[2] They were initially screened by a detailed questionnaire and underwent a complete physical examination. Nonrunning women (n = 5) had normal menstrual histories and did not exercise excessively. No prescribed medications or oral contraceptives were used by any of the subjects for at least 6 months before the study. Runners were required to have run a minimum of 25 miles/wk for at least 12 months before the study. Four of the five eumenorrheic runners had competed in marathons and 10 km races on a regular basis,

whereas three of the four oligomenorrheic runners and four of the five amenorrheic runners also regularly competed in similar distance races. Eumenorrheic runners had regular cycles (mean 28.4 days, range 28 to 29 days), oligomenorrheic runners had cycle intervals of 55.5 days (range 45 to 72 days), and amenorrheic runners did not menstruate for an average of 17 months (range 6 to 36 months). All runners had regular menstrual cycles before the start of serious training. The subjects were similar in age, height, percentage body fat, age of menarche, and weekly running mileage. However, the amenorrheic runners were lower in weight compared with the others ($p < 0.05$, Table I). The runners with menstrual dysfunction had previous hormonal evaluations that ruled out other causes for their irregular menses; they also had no associated medical conditions that could be responsible for their menstrual dysfunction.

Study protocol. All subjects with the exception of the amenorrheic runners were admitted during the midfollicular phases (days 5 to 10) of their menstrual cycles. The subjects were asked to avoid caffeine on the days of the study. They had low-protein breakfasts and did not eat or drink for 4 hours before the study. Each subject had skin fold thicknesses measured from the triceps, suprailiac, and anterior midthigh regions using a Lange caliper. Percentage of body fat was then determined by the method of Pollack et al.[7] All exercise studies were initiated between the hours of noon and 3:00 PM. An 18-gauge heparin lock was placed in the forearm 45 minutes before the study. The subjects were asked to stand for 10 minutes before measurements of baseline blood pressure and heart rate were recorded. Exercise was performed on a Quinton Model 844 Unitwork upright bicycle ergometer. Subjects sat on the bicycle for 30 minutes before the start of the exercise. On day 1, the subjects were asked to cycle starting at a work load of 200 kg-m/min, which was increased by 200 kg-m/min every 2 minutes until the subject could not continue because of exhaustion. Heart rate was monitored by a heart monitor (Electronics for Medicine, White Plains, N.Y.) continually throughout the exercise and rest phases. Blood pressure was taken with a blood pressure cuff and recorded every 2 minutes. Blood was obtained at baseline and every 8 minutes during the exercise period; a final sample was obtained at the time of exhaustion. Blood was obtained at 2, 5, 15, 30, and 60 minutes during the postexercise period as the subject sat quietly in an upright position.

The second day of the study was designed to assess

responses to a submaximal aerobic exercise regimen. The method of Karvonen et al.[8] was used to approximate percentage Vo_2 max and this method is accurate to within ±12%. Sixty percent of the difference between the baseline heart rate and maximal heart rate achieved on day 1 was added to the baseline heart rate to calculate the heart rate to be attained. The subject cycled for 30 minutes against variable resistance to maintain this calculated heart rate at approximately 60% Vo_2 max. She then cycled at a heart rate approximating 80% Vo_2 max for another 15 minutes. Blood was obtained via the heparin lock 0, 20, and 45 minutes during the exercise phases. At the end of the 45-minute exercise session, the subject sat in an upright position for 30 minutes while blood sampling was performed at 2, 5, 15, 30 minutes of the postexercise period.

Assay. The catecholamine levels were analyzed by high-performance liquid chromatography with electrochemical detection (Bioanalytical Systems, Inc., West Lafayette, Indiana). Samples were extracted with aluminum before assay. Recovery of the internal standard, 3,4-dihydroxybenzylamine, was 59% ± 8% (mean ± SD) during the assay period. Levels of prolactin, estradiol, progesterone, luteinizing hormone, and follicle-stimulating hormone were measured by radioimmunoassay. The intra-assay and interassay coefficients of variation were prolactin 7.0%, 12.0%; estradiol 8.6%, 13.4%; progesterone 9.0%, 13.6%; luteinizing hormone 8.6%, 13.4%; and follicle-stimulating hormone 9.5%, 15.5%, respectively. Plasma lactate was measured by an autoanalyzer.

Statistical methods. All data were entered into the data management CLINFO system of the Clinical Research Center. One-way analysis of variance with the Newman-Keuls aftertest was performed for patient profile and cardiovascular data. Either one-way analysis of variance or nonpaired Student *t* tests were performed on nontransformed and log-transformed data obtained during the exercise and rest periods. The results were considered significant at $p \leq 0.05$.

Results

Baseline endocrine profile. The baseline endocrine profile was similar for the four groups (Table II). There were no significant differences in baseline prolactin, estradiol, follicle-stimulating hormone, and luteinizing hormone values or in the luteinizing hormone to follicle-stimulating hormone ratios, although the estradiol levels were lower in the amenorrheic women. All the cycling women were evaluated during the follicular phase as confirmed by progesterone levels <1.0 ng/ml.

Cardiovascular. Baseline heart rates of nonrunning

women, 74.0 ± 2.2 (±SEM) bpm, were significantly higher ($p < 0.05$) than the baseline heart rates of the eumenorrheic running women (59.0 ± 5.3 bpm at 6:00 PM), the oligomenorrheic running women (59.3 ± 3.4 bpm at 6:00 PM), and the amenorrheic women (57.5 ± 2.9 bpm at 6:00 PM). All achieved a maximum heart rate higher than 160 bpm on the day of maximal exercise, and there was no difference in the maximum heart rate achieved. The time required to achieve exhaustion on day 1 varied among the four groups of women (nonrunning eumenorrheic women, 12 to 16 minutes; eumenorrheic women, 16 to 25 minutes; oligomenorrheic women, 20 to 24 minutes; and amenorrheic women, 16 to 20 minutes).

Plasma lactate was measured before exercise and at 5 minutes of the postexercise period. Plasma lactate levels increased sixfold to ninefold in all subjects exercising on day 1, reflecting significant anaerobic work. Mean ± SEM lactate levels after exercise ranged from 5.9 ± 1.4 to 8.8 ± 1.2 mEq/L in the four groups and were significantly higher than baseline levels ($p < 0.05$) for all groups on day 1. The plasma lactate levels after submaximal exercise were minimally increased in each group (mean values ranging from 1.5 ± 0.4 to 2.7 ± 0.5 mEq/L), which confirmed that primarily aerobic work was performed. Notably, only the eumenorrheic running women had significantly higher lactate levels after submaximal exercise compared with baseline level (2.3 ± 0.4 versus 1.0 ± 0.1 mEq/L; $p < 0.05$).

Plasma epinephrine

Day 1. Plasma epinephrine levels increased during maximal exertion sixfold to eightfold above resting levels in all four study groups ($p < 0.001$; Table III) and returned to baseline by 60 minutes. The peak elevation of epinephrine in response to maximal exertion was similar for all groups.

Day 2. Plasma epinephrine levels for all groups increased twofold to threefold from baseline levels for submaximal exercise ($p < 0.001$; Table IV). The epinephrine responses were less than half of those found during maximal exertion. Epinephrine levels returned to baseline by 15 minutes, and no differences were found in epinephrine responses between groups.

Plasma norepinephrine

Day 1. Plasma norepinephrine values increased fivefold to eightfold for the four groups after maximal exertion ($p < 0.001$; Table V). Women runners with menstrual dysfunction had a significantly higher percentage change from baseline to peak levels for norepinephrine levels than did eumenorrheic runners and control subjects ($p < 0.02$, Fig. 1). Thirty minutes after

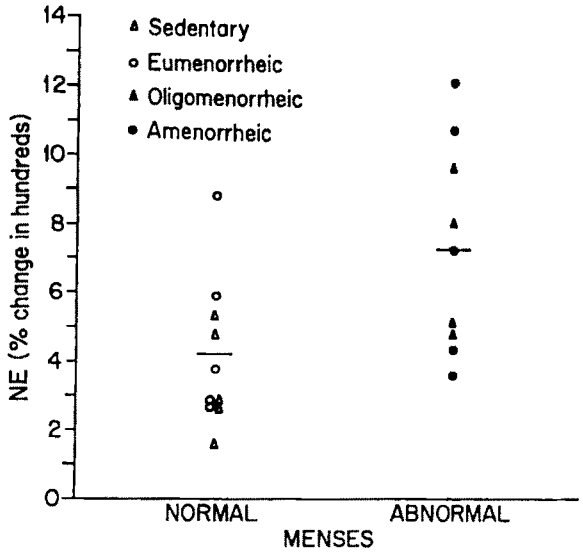

Fig. 1. Women runners with abnormal menses had significantly ($p < 0.02$) elevated plasma levels of norepinephrine *(NE)* during maximal exercise when compared with sedentary women and women runners with normal menses. The data are expressed as percentage increase of norepinephrine over preexercise levels.

exercise, norepinephrine levels had returned to basal concentrations for all groups.

Day 2. Plasma norepinephrine concentrations were threefold greater than their respective baseline values at the end of the submaximal exertion periods for all groups ($p < 0.001$; Table VI). The mean norepinephrine levels returned to basal concentrations 30 minutes after exercise in each group. No differences in norepinephrine levels were found between the groups.

Plasma dopamine

Days 1 and 2. Plasma dopamine levels increased twofold for both exercise protocols ($p < 0.001$, Tables VII and VIII), with recovery to baseline occurring within 15 minutes for both days. There were no significant differences in peak dopamine levels between groups.

Comment

The women in this study had dramatic increases in their plasma norepinephrine and epinephrine levels during maximal exercise. Several women runners achieved norepinephrine and epinephrine values as high as 4000 to 6100 and 1000 to 1100 pg/ml, respectively, a ninefold increase for norepinephrine and a 15-fold increase for epinephrine over basal levels. These levels are higher than previously reported,[4] most likely because the samples were obtained during exercise rather than immediately after its cessation. In our study plasma norepinephrine and epinephrine levels decreased by more than 50% at 2 minutes after exercise. Catecholamine levels were significantly higher for the exercise-to-exhaustion regimen than for the submaximal exercise regimen ($p < 0.001$). This finding is consistent with a report showing that anaerobic activities place a greater demand on the sympathoadrenal system than do aerobic activities.[9]

During the maximal but not submaximal exercise regimen, the percentage change of norepinephrine from baseline to peak levels was greater for oligomenorrheic and amenorrheic runners than for eumenorrheic runners and sedentary women ($p < 0.02$). Graded infusion studies in humans have demonstrated that norepinephrine in the 1500 to 2000 pg/ml range can produce alterations in the metabolic and cardiovascular systems.[5] During vigorous exercise norepinephrine assumes the role of a hormone reaching levels capable of impairing carbohydrate and lipid metabolism, in addition to increasing heart rate and cardiovascular tone.

Norepinephrine has been found to play a dual role in the control of luteinizing hormone release, since both stimulation[10] and inhibition[11, 12] of luteinizing hormone secretion have been described in animal studies. The ability of norepinephrine to have both excitatory and inhibitory effects on luteinizing hormone release has been attributed to its effect on different subpopulations of adrenoceptors, α_1,[13] α_2,[11] and β.[14] A certain basal level of adrenergic neurotransmission is thought to be required to activate the excitatory α-adrenergic receptor population on the luteinizing hormone–releasing hormone neuron for the maintenance of normal pulsatile luteinizing hormone release.[13] However, a relatively large increase in norepinephrine, such as intraventricular infusion[11] or electrical stimulation of brain norepinephrine pathways,[12] may result in an abrupt interruption of the normal pulsatile luteinizing hormone release. Perhaps the women runners in this study with menstrual dysfunction undergo a similar disruption in luteinizing hormone pulsatility from an acute rise in norepinephrine during maximal exercise. The data of Veldhuis et al.[15] support this hypothesis in that their women runners with exercise-associated menstrual dysfunction were found to have a decrease in luteinizing hormone pulse frequency compared with eumenorrheic runners.

An additional explanation is available regarding how an increase in plasma catecholamines could alter the menstrual function of these women runners. Catecholamines have been reported to inhibit the degradation of β-endorphins by blocking the activity of enkephalin aminopeptidase. This finding is potentially important in that β-endorphins can reduce the pulse frequency of luteinizing hormone release[16] and therefore provide an additional mechanism by which elevated plasma catecholamine levels during exercise could influence menstrual function.

*Values are the mean ± SEM.

In summary, we have found that women runners have a marked elevation of plasma catecholamine levels during maximal exercise and that norepinephrine levels were significantly higher in the runners with menstrual dysfunction. We propose that norepinephrine may work in concert with other factor(s) to produce menstrual dysfunction in women runners.

We express our appreciation to the staff of the Clinical Research Center—Dr. Bob Rice, Brenda Bossett, R.D., Connie Boles, and the nurses for their excellent assistance in this investigation—and to Cindy Smithson and Gigi Stomps for their editorial assistance.

Treatment of menorrhagia with meclofenamate sodium

Joyce M. Vargyas, M.D., Joseph D. Campeau, M.S., and Daniel R. Mishell, Jr., M.D.
Los Angeles, California

A double-blind, placebo-controlled crossover trial was undertaken to determine the efficacy of meclofenamate sodium in the treatment of menorrhagia. Twenty-nine patients who had a baseline menstrual blood loss greater than 60 ml received 2 months' each of meclofenamate sodium, 100 mg by mouth, three times a day, or a placebo. The mean menstrual blood loss was reduced from 141.6 ± 15.9 ml at baseline to 69.0 ± 6.3 ml during treatment cycles but remained increased during placebo cycles (135.6 ± 11.3 ml). The symptoms of dysmenorrhea, backache, and headache were significantly reduced only during active drug periods. The number of days of flow and pads or tampons used was also reduced during drug cycles but not during placebo cycles. Overall, 26 of the 29 patients evaluated had a reduction in menstrual blood loss with the use of meclofenamate sodium. It appears that many women with unexplained menorrhagia may benefit from this treatment. (Am J Obstet Gynecol 1987;157:944-50.)

Key words: Menorrhagia, prostaglandin inhibitors, meclofenamate sodium

The average blood loss at the time of menses is estimated to be between 20 and 60 ml. There appears to be an increased incidence of iron-deficiency anemia if blood loss exceeds this amount.[1] A statistically significant number of women will have hemoglobin concentrations of <12 gm/dl when menstrual blood loss exceeds 80 ml.[1] Many of these women have no identifiable, organic, or endocrinologic explanation for their menorrhagia.

The endometrium of women with menorrhagia has been found to have higher levels of prostaglandin E_2 and prostaglandin $F_{2\alpha}$ when compared with women with normal menses.[2] Furthermore, it has been hypothesized that the increase in prostaglandin E_2 production and binding coupled with the vasodilatory action of prostaglandin E_2 may be the pathophysiologic explanation for the menorrhagia in patients with an otherwise unknown cause for the blood loss.[3]

The subgroup of prostaglandin inhibitors known as the fenamates act by both inhibiting the biosynthesis of the cyclic endoperoxides and by blocking prostaglandin E_2 and prostaglandin $F_{2\alpha}$ directly at the receptor sites. Anderson evaluated the effect of mefenamic acid therapy in 22 patients with menstrual blood loss of >80 ml. Twenty patients demonstrated a 2% to 78% reduction in blood loss with therapy.[4] Fraser et al.[5] undertook a 4-cycle, double-blind, randomized, placebo-controlled crossover trial and found that in the 30 patients studied, the mean blood loss that occurred during mefenamic acid treatment cycles was 28.1%.

With these findings in mind, we sought to determine the efficacy and safety of meclofenamate sodium (Meclomen). This study was undertaken to determine whether meclofenamate sodium was effective in treating women with menorrhagia of unknown etiology with the use of 4-month double-blind crossover trial.

Patient selection

Patients who were 16 to 42 years old with a definite history of menorrhagia and a negative pregnancy test were entered into a 2-month observation period to confirm the diagnosis and evaluate the possible cause. During this period, the patients underwent a complete history and physical and a late luteal phase endometrial biopsy. In addition, a complete blood count, erythrocyte sedimentation rate, serum ferritin, serum

glutamic-pyruvic transaminase, blood urea nitrogen, T_3, T_4, and urinalysis were performed. They collected all sanitary napkins and tampons during two menstrual periods, which were subsequently assayed for menstrual blood loss by the alkaline hematin method.[6] Baseline laboratory parameters included a complete blood count, erythrocyte sedimentation rate, serum ferritin, serum glutamic-pyruvic transaminase, blood urea nitrogen, T_3, T_4, and urinalysis.

Patients were excluded from the study if they had anovulatory cycles (proliferative endometrium) or histologic evidence of pathologic changes in the endometrium (hyperplasia or atypia). They were also excluded if a physical examination revealed that they had an extrauterine disease or palpable leiomyoma. Other criteria for exclusion included a known sensitivity to fenamates, anticoagulant therapy, thyroid dysfunction, hepatic disease, renal disease, or abnormal cervical cytologic findings.

Women who did not have any of these pathophysiologic processes and demonstrated a menstrual blood loss >60 ml in at least one observation cycle were enrolled in the study.

Methodology

Experimental design. Patients who met inclusion criteria were randomly assigned in a double-blind manner to one of two groups by code supplied by an independent biometrics department. The Meclomen group received 100 mg of meclofenamate sodium three times a day during the next two menstrual cycles and were then crossed over to receive an identical-appearing placebo capsule three times a day for the last two menses. The placebo group received the placebo capsules for the first two menses and were then crossed over to receive Meclomen for the last two menses.

Medication was initiated after the onset of menses and continued three times a day for 6 days or until the cessation of menses, whichever came first. During menses, patients collected all tampons and sanitary napkins in a sealed, dry container. The collected material was assayed for menstrual blood loss at the end of each menses.

Patients kept their own diaries, which included the number of days of menstrual flow, medication records, the use of concurrent medications, and the occurrence of side effects or dysmenorrhea.

Patients underwent a history, physical, and evaluation of all the laboratory parameters before the initiation of the study and after the 4-month trial period ended. A complete blood count, platelet count, mean corpuscular volume, and mean corpuscular hemoglobin concentration were also analyzed on the sixth day of the first treatment cycle, the cycle before crossover, and in the final cycle.

Pads and tampons were analyzed for the amount of blood loss at the end of each collection period. The assay was performed as previously described[7] by extraction of blood from pads and tampons by soaking in sodium hydroxide for 24 hours. The blood was then filtered through a Whatman No. 1 filter paper to remove fibers. The measurement of the hemoglobin concentration from the extracted blood was performed by spectrophotometry at an optical density of 546 mm. The concentration of hemoglobin was then compared with the hemoglobin concentration in a known volume of venous blood to calculate the volume of blood loss.[7]

Statistical analysis. The primary measure of effectiveness was based on the ability of the drug to reduce menstrual blood loss. For the baseline analysis of two treatment groups, a one-way analysis of variance was used. The overall significance level was 5% for all statistical evaluations performed.

To compare the overall blood loss and decrease in blood loss from baseline during drug cycles with blood loss during placebo cycles in both groups of patients, a two-treatment four-period crossover analysis of variance was used. This type of analysis was also used to compare pad and tampon use, duration of menstrual flow in days, and severity or occurrence of prostaglandin-related symptoms, such as dysmenorrhea, backache, headache, nauesa, and/or vomiting.

Independent t tests with a Bonferroni correction factor were used to analyze individual comparisons of menstrual blood loss and decreases in blood loss from baseline levels. The overall significance level was adjusted to 1.25% for the evaluations performed.

Subjects were classified into one of three categories to evaluate the percentage distribution of patients who experienced a reduction of blood loss from baseline during Meclomen cycles. A χ^2 test was used for this analysis. The categories were divided into those patients who had a decrease in blood loss from baseline during both Meclomen cycles, those who had a decrease from baseline in one Meclomen cycle, and those who did not have a decrease in blood loss during any Meclomen treatment period.

Study population. Of 95 patients who underwent the screening process, 32 women qualified on the basis of the previously stated criteria and were entered into the study. Of these women, 15 were randomly assigned to the Meclomen-placebo group and 17 to the placebo-Meclomen group. The mean age, body weight, and race distribution were similar in both groups (Table I).

Of the 32 women, three had a past history of anemia and three others had concurrent medical conditions that did not exclude them from the study. The latter three patients included one with hypothyroidism who was taking replacement therapy, another with a history of hypertension that occasionally required treatment

Table I. Characteristics of patients enrolled in each treatment group

	Mean age (yr) (range)	*Mean weight (lb) (range)*	*Race*	
			White	*Black*
Meclomen (n = 15)	36.4 (19-45)	149.3 (108-213)	12	3
Placebo (n = 16)	35.3 (29-43)	164.7 (120-130)	13	3

with hydrochlorothiazide, and one receiving isoniazid (INH) therapy for a positive tuberculosis test.

All patients had regular cycle bleeds with no intermenstrual spotting, 10 (31%) had severe dysmenorrhea, 16 (50%) had moderate dysmenorrhea, and six (18%) are or were dysmenorrheic.

All but four patients had one or more living children, seven (21%) were currently using an intrauterine device for contraception, six (18%) had undergone previous sterilization procedures, and two (15%) used barrier methods. Eleven women either had partners with vasectomies or were not sexually active.

Two patients discontinued the study after the screening phase for personal reasons. Another patient discontinued the study because of gastric distress after one cycle of Meclomen. Twenty-nine women completed the 4-month double-blind trial and are included in the final statistical analysis. The Meclomen-placebo group included 13 patients and the placebo-Meclomen group included 16 patients.

Results

The mean baseline menstrual blood loss was 141 ± 17.5 ml in group 1 and 141.8 ± 26.5 ml in group 2, which did not differ significantly. The menstrual blood loss during the Meclomen treatment periods (69.0 ± 6.3 ml) was significantly less than the blood loss during the baseline screening cycles (141.6 ± 15.9 ml) and the placebo cycles (135.6 ± 11.3) ($p < 0.0001$) (Fig. 1).

The mean blood loss during the trial cycles is seen in Fig. 2 and is graphed sequentially according to cycle treatment period and treatment group. Blood loss was significantly reduced during the Meclomen cycles when compared with the placebo cycles for periods 1, 2, and 3. The mean blood loss during the Meclomen treatment periods ranged from 58.3 ± 11.5 ml in cycle 3 to 81.2 ± 15.8 ml in cycle 1. The mean blood loss during the placebo periods ranged from 117.3 ± 23.5 ml in cycle 4 to 156.6 ± 24.4 ml in cycle 1. There was no demonstrable order effect whether drug or placebo was administered first and no residual effect from previous treatment periods.

The percentage change from baseline is shown in Fig. 3 according to treatment period and group. The overall decrease in blood loss was significantly greater during the Meclomen treatment periods (−48.9 ± 3.7) than during the placebo treatment periods (−9.2 ± 5.3; $p < 0.0001$). Blood loss was significantly reduced during individual treatment periods 1, 2, and 3. The percentage change in blood loss ranged from −42.4% ± 3.0% in cycle 1 to −55.8% ± 8.3% in cycle 3 during Meclomen administration and from

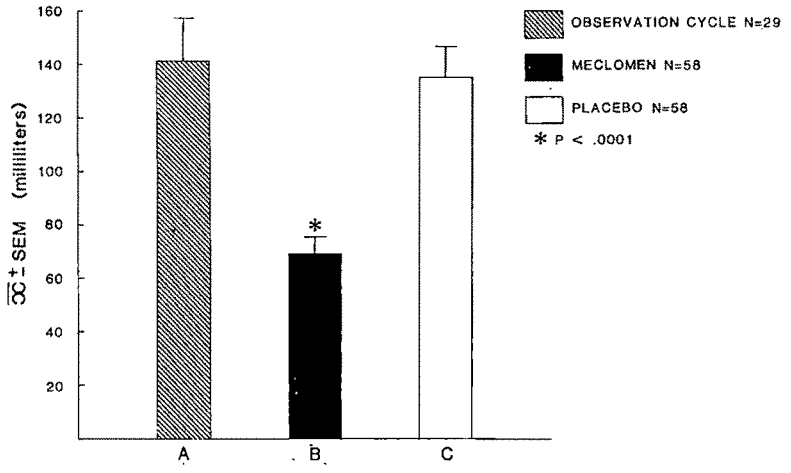

Fig. 1. Menstrual blood loss.

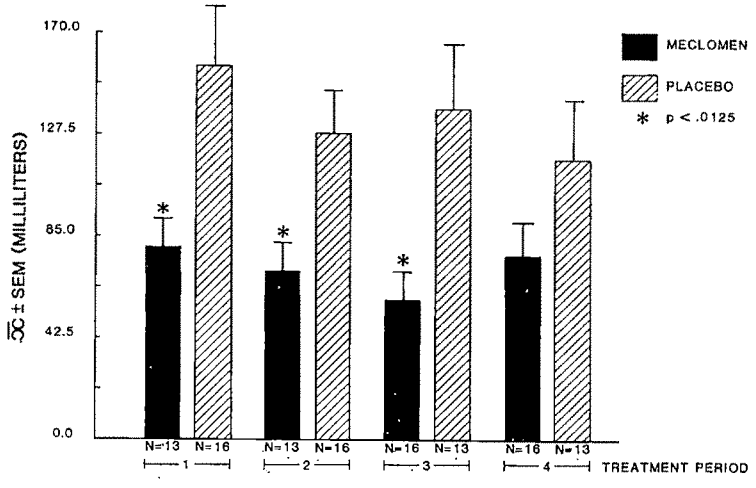

Fig. 2. Menstrual blood loss by treatment period and drug.

−26.0% ± 9.1% in cycle 4 to +5.8% ± 11.9% in cycle 1 during placebo cycles. There was no demonstrable order effect whether drug or placebo was administered first and no residual effect from previous treatment periods.

The number of patients who experienced a decrease in blood loss during both one or no treatment cycles is seen in Table II. There was a statistically significant difference in the Meclomen response pattern when compared with the placebo response pattern.

Pad and tampon use per menstrual cycle and the number of days of menstrual flow are summarized in Table III. During Meclomen cycles, the mean number of pads and tampons used per patient per day was less than the number used in placebo and baseline cycles ($p < 0.0001$). Likewise, it was found that the duration of flow was significantly less during Meclomen cycles (4.8 ± 0.0) when compared with placebo (5.5 ± 0.18) or baseline cycles (6.3 ± 0.41; $p < 0.0003$).

Table V. Median hemoglobin, hematocrit, and ferritin levels in all subjects before and at end of study

	Baseline	*Study termination*
Hemoglobin (gm/dl)	13.2	12.8
Hematocrit (%)	39.4	38.9
Ferritin (ng/ml)	16.0	14.8

The severity of prostaglandin-related symptoms was rated by patients on a daily basis from none = 0 to severe = 3. The results are summarized in Table IV. The severity of dysmenorrhea, backache, and headache while patients took Meclomen was significantly less than

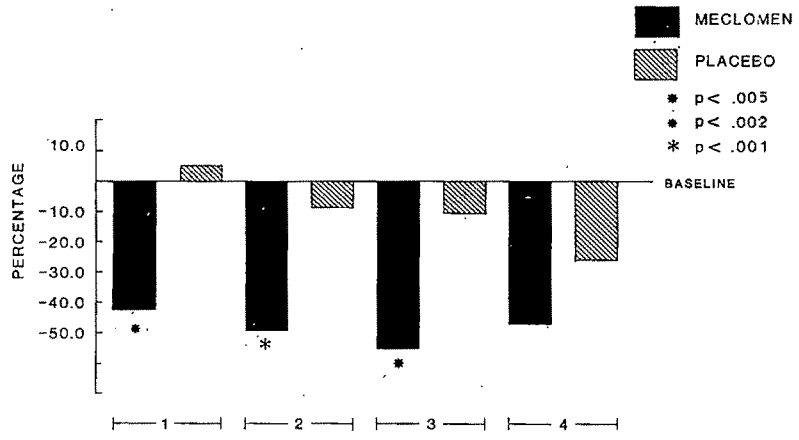

Fig. 3. Percentage change from baseline in blood loss by treatment period and drug.

that while patients took the placebo. There was, however, no difference in nausea or vomiting when ratings during the Meclomen and placebo cycles were compared.

The median hematocrit, hemoglobin, and serum ferritin levels in groups 1 and 2 were similar at the onset of the study. The overall median hematocrit/hemoglobin was 39.35/13.15. These parameters remained unchanged throughout the 4-month study, and levels were not significantly altered after treatment. Likewise, serum ferritin levels were similar at baseline and remained stable throughout the study (Table V).

Five patients experienced side effects while taking Meclomen. Four patients had episodes of nausea and vomiting that may have been related to the drug or prostaglandin release at the onset of menses. One patient had a 3-day episode of epigastric distress after ingestion of the medication on an empty stomach.

Comment

Many women have menorrhagia of unexplained origin. The disorder has been estimated to occur in 2% to 10% of the female population.[7] Although the pathophysiologic mechanisms responsible for the excessive blood have not yet been definitively identified, recent data implicate elevated levels of prostaglandin E_2 and prostacyclin in the endometrium as potential etiologic factors.[8]

Luteal phase endometrial levels of prostaglandins are increased in women with regular but excessively heavy menses when compared with levels in women with normal menses.[2] The increase in prostaglandin E is significantly greater than that for prostaglandin$_{2\alpha}$.[2] Moreover, the follicular phase levels of the endometrial prostaglandins are also elevated unlike those in women with normal menses or dysmenorrhea in whom a cyclic variation is demonstrated.[2] The data imply chronically elevated levels of endometrial prostaglandin E in this subgroup of women. Although peripheral steroid levels do not demonstrate an endocrine disregulation as the cause of menorrhagia, an altered endocrine response of the endometrium may be hypothesized as a causative factor.

Other data that support this theory is found when endometrial receptor profiles are evaluated. Hoffman et al. showed that receptor binding for prostaglandins E and $E_{2\alpha}$ is highest in the fundus of the uterus and correlates with the amount of smooth muscle content found in the sample. When different gynecologic conditions were compared, there was no difference in prostaglandin $E_{2\alpha}$ binding. However, prostaglandin E binding was significantly elevated when uteri from patients with abnormal uterine bleeding are compared with those from patients with dysmenorrhea.[3]

Women using an intrauterine contraceptive device have an increase in menstrual blood loss. In one series, 47.7% of women had a blood loss >80 ml, and all women increased their blood loss by 106% after insertion.[9] Likewise, when the prostaglandin content of the endometrium is evaluated before and after insertion of the intrauterine device, a statistically significant increase in prostaglandin E but not E_2 is found in 11 of the 14 patients evaluated.[10] Mefenamic acid has been shown to reduce intrauterine device–associated menstrual blood loss.[4] In our series, five of the seven women who were intrauterine device users also had a reduction of blood loss when meclofenamate sodium was compared with blood loss during baseline or placebo cycles.

Several pathophysiologic properties of prostaglandins may account for their role in the etiology of menorrhagia. Prostaglandin E has been shown to be a potent vasodilator and an inhibitor of platelet aggregation and adhesiveness.[11, 12]

Likewise, the prostaglandin endoperoxide prostaglandin H_2 is transformed into thromboxane A_2 and prostacyclin (prostaglandin I_2). Prostacyclin, like pros-

taglandin E, causes vasodilatation and also prevents the aggregation of platelets by increasing cyclic adenosine monophosphase. On the other hand, thromboxane results in vasoconstriction and platelet aggregation, which possibly negates the effect of prostacyclin.[11, 12]

However, prostacyclin appears to be the main by-product of arachidonic acid when measured after incubations of endometrium and myometrium.[13] When endometrium from women with normal menses and heavy menses (>50 ml) is incubated with control myometrium, a significantly greater amount of *p* 6-oxy-prostaglandin F_1, the stable metabolite of prostacyclin, is produced.[13] If the in vitro increase in conversion of endoperoxides from the endometrium to 6-oxy-prostaglandin F_1 in the myometrium occurs in a similar fashion in vivo, the excessive formation of prostacyclins may then be implicated as an additive factor in the etiology of menorrhagia.[8]

The anti-inflammatory actions of the prostaglandins are thought to result from the inhibition of prostaglandin E_2 and prostacyclin.[14] The ability of certain prostaglandin inhibitors may also be the result of their ability to reduce the levels of these substances and menstrual blood loss. Meclofenamate sodium has been found to inhibit prostaglandin E_2 formation in bovine seminal vesicles to a significantly greater degree than naproxen, ibuprofen, and benoxaprofen (25→200 × >). The effect was similar to indomethacin.[15] The increased potency of meclofenamate sodium in the reduction of prostaglandin E_2 may account for its efficiency in the reduction of menstrual blood loss.

Overall, the results of this study clearly indicate that meclofenamate sodium decreases the volume of menstrual blood loss in patients with a blood loss >60 ml and no clinically identifiable uterine disease or endocrine abnormality. Twenty-six of the 29 patients evaluated had a reduction in blood loss ranging from 15% to 91% during active drug periods. Therefore it may be anticipated that about 90% of patients will have a good clinical response to treatment with meclofenamate sodium.

Seventeen of the 29 women studied had a blood loss of <80 ml and 12 of the 29 women had a blood loss of <60 ml during both drug administration periods. Three additional patients had a blood loss of <60 ml, and one patient had a blood loss of <80 ml during one of the two medication periods. Halberg et al.[1] showed that although there was some reduction in mean corpuscular hemoglobin concentrations in women with a blood loss >60 ml, the mean peripheral hemoglobin concentrations did not decrease significantly until menstrual blood loss was >80 ml. Therefore it can be anticipated that approximately 60% to 72% of women will not be at risk for anemia with this treatment regimen even without iron supplementation.

The lack of a statistically significant difference in mean blood loss and percentage decrease from baseline between meclofenamate sodium and the placebo during the fourth treatment period is most likely caused by the cycle-to-cycle variation in patients, which has been demonstrated by several investigators.[16] Haynes et al.[16] found that cycle-to-cycle variation was greater in patients with menorrhagia (39 to 271 ml) than in women with normal menses. This factor most likely influenced the fourth-period placebo response and the difference in the statistical evaluation for this treatment period.

Three of the 29 patients evaluated in our study did not demonstrate a reduction in blood loss when compared with baseline measurements. All three patients used an intrauterine device for contraception during this study. The resistance of some intrauterine device users to treatment may be related to the importance of endometrial fibrinolysis in intrauterine device–associated menorrhagia as evidenced by the effective treatment with a fibrinolysis inhibitor (tranexamic acid).[11]

In clinical practice, it is not feasible to measure menstrual blood loss to determine the efficacy of the medication. However, in our study, the number of days of flow and pads and/or tampons used was significantly decreased during the medication periods when blood loss was reduced. Some of these indicators of blood loss have been found to correlate with actual blood loss by previous studies but not consistently. These parameters may be used as soft indicators of blood loss, and if combined with the patient's subjective assessment and serum hemoglobin levels, it is feasible to evaluate the effect of meclofenamate sodium on blood loss and differentiate those patients who may benefit from the medication from those who might warrant further diagnostic and/or therapeutic measures.

Configuration of the prepubertal hymen

Susan Ferrell Pokorny, M.D.
Houston, Texas

Anatomically descriptive terms are required when one is asked to comment on the hymen of the sexually abused prepubertal child. Action descriptive terms such as virginal or ruptured relay no objective information. Biologic hymenal configurations can be loosely categorized by the amount and distribution of hymenal tissue surrounding the vaginal introitus: The terms fimbriated, circumferential, and posterior rim are proposed. Descriptions of 124 prepubertal hymens are presented, with discussion focusing on biologic configurations and the impact of trauma and hormones. (Am J Obstet Gynecol 1987;157:950-6.)

Key words: Hymen, sexual abuse, prepubertal, biologic configurations

Abnormal variations in hymenal configurations such as the imperforate, the cribriform, the septate, and the microperforate hymen are well documented.[1, 2] Variations in normal hymenal configuration have also been noted[1, 3-6] and can be loosely categorized by the amount and distribution of hymenal tissue surrounding the vaginal introitus.

The most abundant amount of tissue appears as a redundant, gathered skirt of hymenal tissue surrounding the vaginal introitus. It has been variously described as "irregular, festonne or dentelle or divided into multiple fingers"[3] or as "fimbriated or irregularly notched in outline."[6]

An intermediate amount of tissue exists when the arrangement of hymenal tissue appears smooth, circumscribing the vaginal introitus without folds and with an annular opening. This type has been called a "ring, generally broadest posteriorly,"[4] "annular,"[7] or "annular with oval central opening."[6]

The hymenal configuration with the least amount of tissue present is arranged in a semilunar fashion as a rim of tissue that extends variously from 1 to 2 o'clock, posteriorly around to 10 or 11 o'clock (anterior is 12 o'clock and posterior is 6 o'clock). This hymenal configuration has no or minimal tissue visualized anteriorly and has been described as "a semilunar fold, with its concave margin turned towards the pubes,"[4] "crescentic in appearance,"[6] "congenitally incomplete,"[8] "narrow rim,"[1] and "semilunar or falciform."[3]

Understanding normal hymenal configurations is crucial to the clinician who is asked to evaluate the genitalia of children who may have been sexually abused. Only by knowing normal anatomy can one make meaningful comments and descriptions about alterations that may have occurred as a result of physical trauma. The current practice of placing emphasis on the diameter of the vaginal or hymenal orifice as an indicator of normality or evidence of sexual abuse in the prepubertal child[1, 8-12] should be discouraged when used as an isolated parameter. Normal variations in the

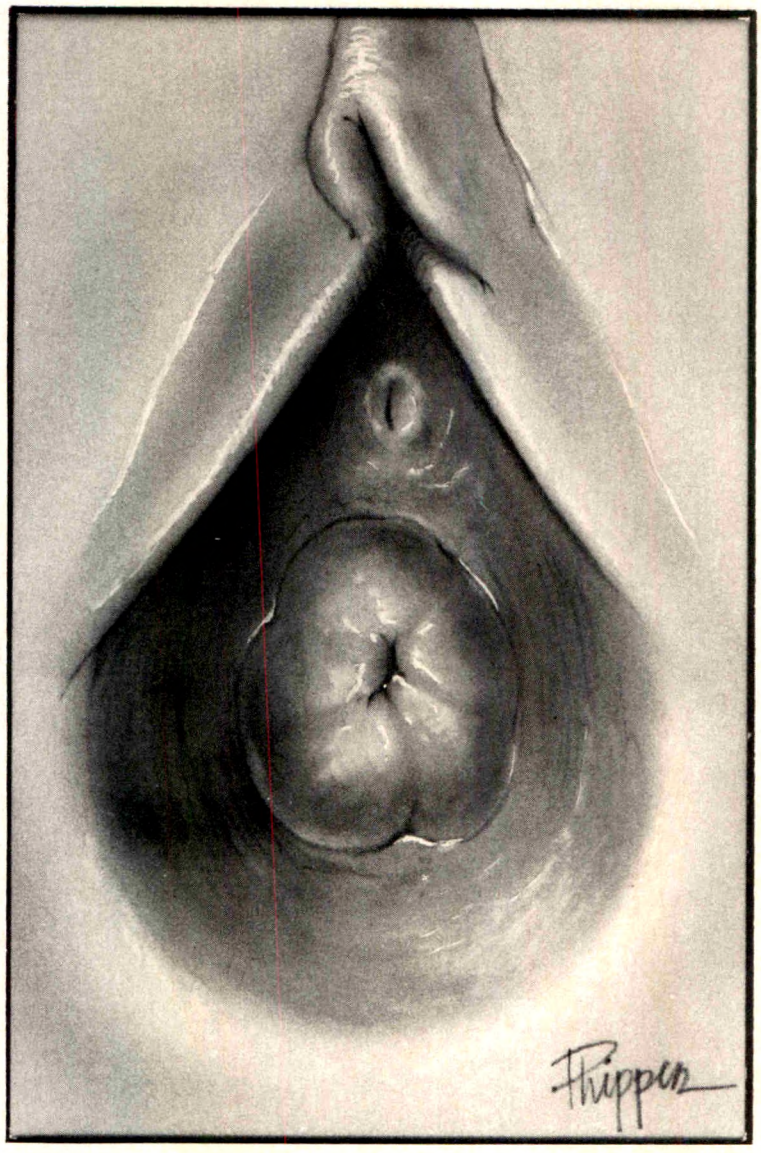

Fig. 1. Fimbriated hymen.

amount and distribution of hymenal tissue will influence the diameter of the vaginal or hymenal orifice.

The hymenal configuration as described in the medical records of 124 prepubertal females is the basis of this article.

Methodology

Anatomic hymenal descriptions were recorded in the medical records of 124 premenarchal female children ages 9 weeks to 10 years. During a 2-year period I saw these patients for a gynecologic examination. The following variables were analyzed: the hymenal configuration, age, race, source of and reason for referral, and any other gross perineal anatomic variation.

For purposes of this study, fimbriated hymens were redundant, gathered skirts of hymenal tissue with scalloped rims (Fig. 1); circumferential hymens were smooth unfolded skirts of hymenal tissue with uniform annular rims (Fig. 2); and posterior rims were crescentic smooth folds of tissue arranged from 2 o'clock through 11 o'clock around the introitus with minimal or no tissue visualized anteriorly (Fig. 3).

Results

The results of age and race distribution are noted in Table I. The white and Hispanic patients were slightly younger than the black patients, although very few patients under the age of 2 years were seen. Referrals came from other physicians, parental initiation, and community children's protective and investigative agencies. Analysis of referral patterns and the reason

*One case of microperforate, two cases of imperforate, six cases of absent or remnants only. Absent or remnants: two cases ages 2 to 4 years, 1 case age 5 to 7 years, and three cases ages 8 to 10 years.

for the visit (Table II) reveals that most patients were referred by other physicians for an evaluation of possible sexual abuse or assault. Vulvovaginitis accounted for another large group of patients. The miscellaneous category included a broad range of entities including the following: labial agglutination, imperforate hymen, ectopic anus, accidental trauma to the perineum, urethral prolapse, premature telarche, and diethylstilbesterol exposure.

In this series (Table III), 25 hymens were classified

Fig. 4. Example of a fimbriated hymen in a 10-year-old child.

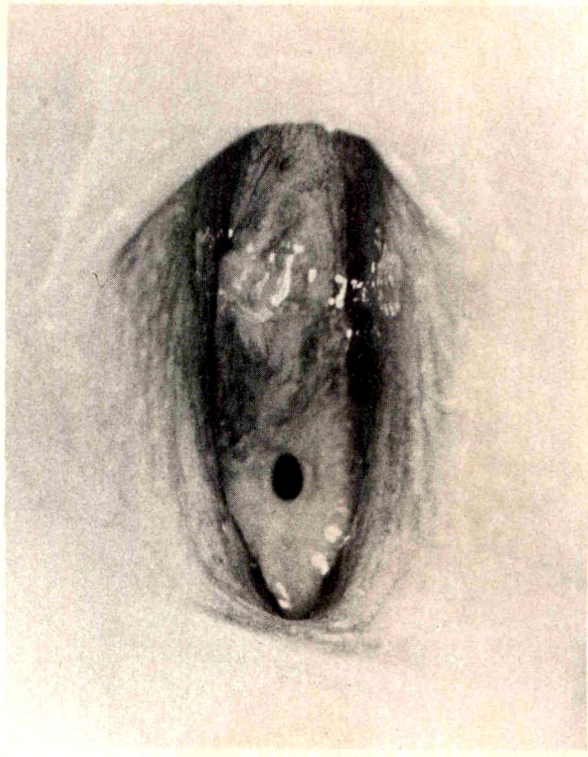

Fig. 5. Example of a circumferential hymen in a 3-year-old girl.

as fimbriated (Fig. 4), 34 as circumferential (Fig. 5), 56 as posterior rim (Fig. 6), and nine as "other." The fimbriated and circumferential configurations were more prevalent in patients less than 4 years of age. There was a fairly even age distribution of those children with posterior rims. In the "other" category, six children were further subcategorized into having absent or remnants of hymen only (Fig. 7). Five of these six children had substantive evidence of sexual abuse; the sixth child, whose grandfather had been accused of molesting other children, was never adequately investigated and was lost to follow-up.

One of the cases listed under fimbriated was a 10-year-old white girl who was at Tanner breast Stage II and pubic hair Stage I when she was violently raped. She underwent surgical repair of a large vaginal laceration and a second-degree laceration of her posterior forchette. On completion of the surgery, the patient was noted to have a prominent rosette of hymenal tissue (fimbriated) surrounding the vaginal introitus. When seen in follow-up 2 weeks later, only small remnants of hymenal tissue remained.

Definite breaks or significant alterations in the hymenal skirt of tissue were noted in 31 children. When reasons for examination were grouped according to those with a strong possibility of being sexually abused (sexually transmitted disease/possible sexual abuse, n = 70) and all others (vulvovaginitis/miscellaneous, n = 54), the suspect sexually abused children were 3.5 times as likely to have a broken and/or altered hymen than the other group. Although all types of hymenal configuration are represented among the children with recorded breaks or alterations, there is a definite trend for breaks to be noticed on hymens with scantier amounts of tissue.

Comment

The hymen is a small organ that surrounds the opening of the vaginal introitus. It is made up of elastic and collagenous connective tissue whose surfaces are covered by stratified squamous epithelium.[3] Its importance to mankind has been predominantly cultural. In the last decade physicians have needed more objective information about the hymen as they have attempted to evaluate their female patients for possible sexual abuse or assault.

The distensibility of the vaginal orifice and its adjacent organs, when under the influence of adult levels of female hormones, makes it difficult for physicians who are requested to testify about the "virginity" of a certain patient.[8] On the other hand, when the hymen is distended by an object as large as an infant's head in the process of childbirth, readily recognizable changes in the hymen occur as it shrivels into what are called the "myrtiform caruncles."[5] Thus we know from observations of the estrogenized hymen that two factors

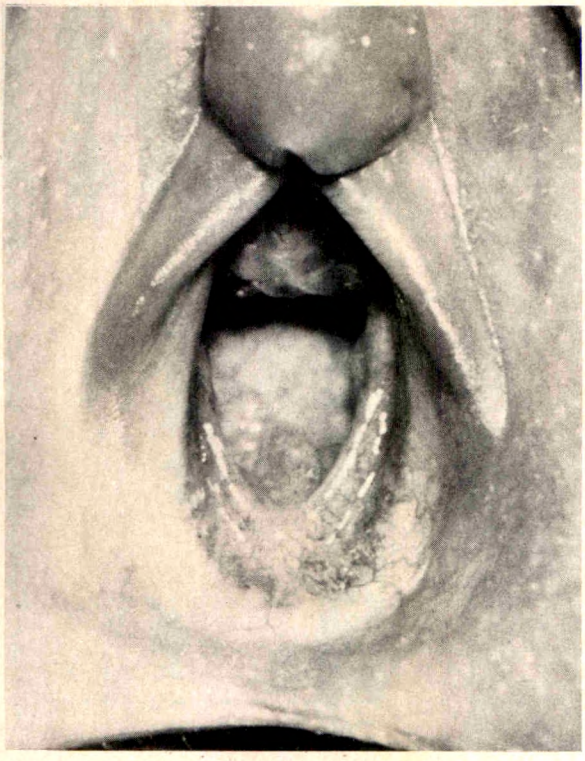

Fig. 6. Example of a posterior rim in a 3-year-old child.

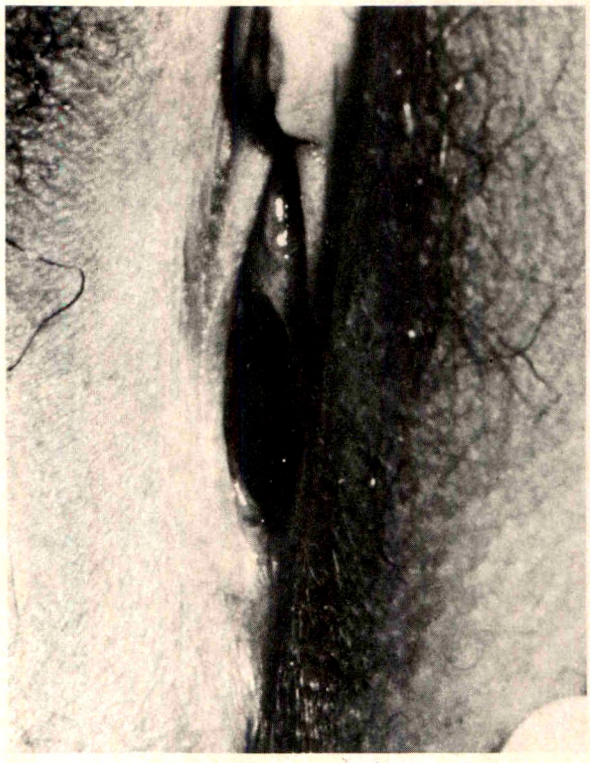

Fig. 7. Example of remnants only in a 7-year-old girl.

influence the hymen configuration: hormones and trauma.

The question must be raised about whether the six children in this series, who were noted to have remnants only, and the one 10-year-old girl who is listed as fimbriated but who had remnants only 2 weeks after surgery, are not in fact the prepubertal equivalent of myrtiform caruncles.

Longitudinal studies will better define the impact of hormonal changes on the hymen. It has been noted[11] that it appears to be less traumatic to examine the vagina of a child less than 2 years old than to perform the same procedure on an older child. This most likely reflects the influence of the maternal estrogen effect on the younger child's hymen, which makes it pink white and thicker as opposed to the unestrogenized hymen, which is redder and much thinner.

A biologic hymen configuration most likely occurs before birth. The hymen is formed at the site where the solid mullerian ducts join the urogenital sinus.[13] It appears that the biologic mechanism for opening the hymen occurs anteriorly. All microperforations are anterior. It has been noted in this series as well as by Gray[4] that there is a tendency for the annular opening of the circumferential hymen to be anteriorly placed, and the posterior rim has minimal or no visible membrane anteriorly. This anterior locus of activity raises the question about whether the perforations of the hymenal membrane are made by the same biologic process that recanalizes the vagina.

The distribution of hymenal configuration by age and type as reported in this article *cannot* be considered a normal population distribution; this study was performed on patients with known or suspected problems. This effort was undertaken to encourage clinicians to develop skills in objective descriptions of the hymen. Action descriptive terms such as virginal, marital, perforated, ruptured, and penetrated relay no objective information. Anatomically descriptive terms are required. I propose three categories based on the amount and distribution of the hymenal tissue: fimbriated, circumferential, and posterior rim.

Configuration is the parameter emphasized in this article. Determining the basic biologic configuration of the prepubertal hymen is seen as a preliminary step before studies can be undertaken to determine changes caused by physical or infectious trauma or hormones. Does a particular biologic hymenal configuration change over time? In this small study, which covered a 2-year period, no changes occurred in the few children who were seen in subsequent visits except for the one 10-year-old rape victim whose fimbriated hymen became remnants only. On the other hand, overall there were more fimbriated and circumferential hymens (i.e.,

a more abundant amount of hymenal tissue) in children less than 4 years of age.

Is there any significance between a high and a low posterior rim? Would gradual, coercive dilation of a child's hymen convert it from a high to a low posterior rim or from a fimbriated or circumferential to a posterior rim?

These and other questions cannot be answered until clinicians learn to identify and discern the anatomic detail of prepubertal hymens and undertake prospective studies.

I would like to thank Claudia Kozinetz for her assistance in compiling the tables.

Suppression of lymphocyte reactivity in vitro by supernatants of explants of human endometrium

Huei-Sheng Wang, M.D., Hideharu Kanzaki, M.D., Masumi Yoshida, M.D., Shigeyasu Sato, M.D., Makoto Tokushige, M.D., and Takahide Mori, M.D.

Kyoto, Japan

To clarify the possible immunologic functions of the endometrium before implantation, supernatants from explant cultures of human endometrial tissues were examined for effects on mixed lymphocyte reaction and phytohemagglutinin M–stimulated cultures. Supernatants obtained from both proliferative and secretory phase endometria showed significant dose-related suppressive effects; the suppressive activity of secretory phase endometria was higher than that of proliferative phase endometria. On the other hand, no inhibitory effect was identified in supernatants from similar cultures of peritoneum and omentum, while supernatants of fallopian tubes showed slight suppressive activity. These results suggest the existence of soluble nonspecific immunosuppressive factor(s) released from human endometrium (especially during the secretory phase), and imply that these factor(s) may exert an important role in protecting the fertilized ovum from maternal rejection. (Am J Obstet Gynecol 1987;157:956-63.)

Key words: Endometrial supernatant, mixed lymphocyte reaction, phytohemagglutinin M, immunosuppression

During the last decade much attention has been focused on local regulation of the maternal immune response in the uterus toward the explanation of how the conceptus avoids immunologic rejection. The uterus is a unique organ of considerable immunologic interest; not only must it deal with constant exposure to the external environment, it must also serve as the recipient site for the natural transplantation of genetically alien spermatozoa and conceptuses, without developing destructive immune responses. A major part of these functions is borne by the uterine endometrium, and

several recent reports have suggested the important immunoprotective role of decidua,[1, 2] the end product of a hormonally induced transformation of the endometrium. However, it is not known whether nondecidualized endometrium also possesses immunoregulatory properties. To clarify the immunologic role of the endometrium, we examined the effects of supernatants obtained from tissue culture of human endometrium on mixed lymphocyte reaction and phytohemagglutinin M–stimulated lymphocyte activation.

Material and methods

Tissue cultures. Human endometrial tissues were obtained at hysterectomy in 28 women aged from 35 to 45 years without malignancy and who had not received hormone therapy for at least two menstrual cycles before the operation. The tissues were washed twice in cold Hanks' balanced salt solution, once in Trowell's T8 medium (Gibco Laboratories, Grand Island, New York), and then cut into pieces of approximately 1 to 2 mm^3. Five to seven pieces of endometrial tissues (100 to 200 mg wet weight) were placed on a sterile stainless mesh in a six-well Petri dish (Falcon 3046, Becton-Dickinson & Co., Oxnard, California) containing 2 ml of Trowell's T8 medium supplemented with 10% heat-inactivated fetal calf serum (Gibco), 100 IU/ml of penicillin G, and 100 μg/ml of streptomycin sulfate. A portion of the tissues was prepared for histologic examination and determination of the menstrual cycle. The tissues were incubated in a humidified atmosphere of 95% air and 5% carbon dioxide at 37° C for 1 hour. Next, the culture medium was discarded to remove cell debris and toxic products, and 2 ml of new culture medium was added. After an additional culture for 12, 24, 48, or 72 hours, the culture medium was centrifuged, collected, and stored at −20° C. Trowell's T8 medium contained 10% fetal calf serum and antibiotics were incubated in the same manner as the medium control. To serve as controls, tissue specimens from the fallopian tube, peritoneum, and omentum from 13 of these patients were treated in the same manner.

Preparation of lymphocytes. Peripheral blood lymphocytes were obtained from healthy male volunteers by Ficoll-Hypaque centrifugation. The separated cells were washed three times in RPMI-1640 medium and resuspended in the same medium (Gibco) supplemented with 10% fetal calf serum and antibiotics as above.

Mixed lymphocyte reaction. Peripheral blood lym-

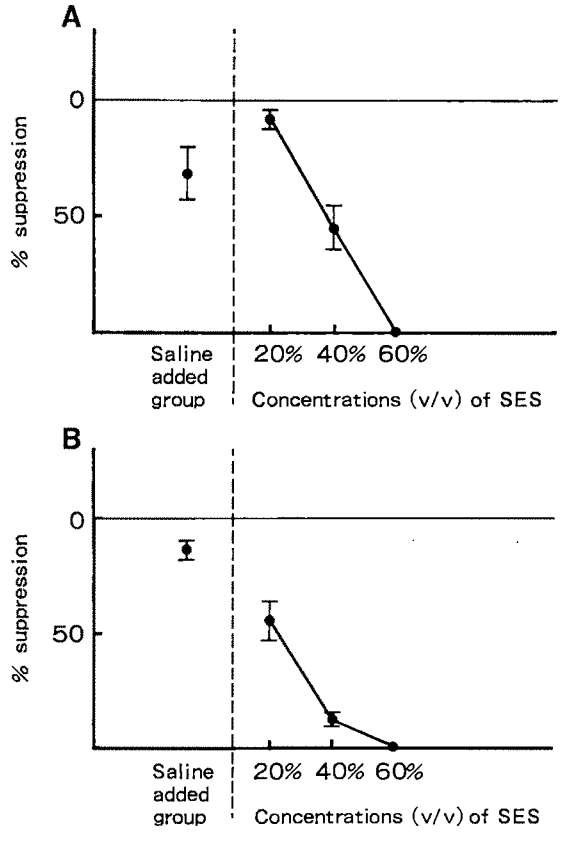

Fig. 2. Dose-dependent suppression by secretory phase endometrium *(SES)* on mixed lymphocyte reaction **(A)** and phytohemagglutinin–induced lymphocyte stimulation **(B)**. Each well contained peripheral blood lymphocytes in a density of 2×10^5/well **(A)** or in a concentration of 1×10^6/ml **(B)** with various concentrations (vol/vol) of secretory phase endometria. Results are expressed as percent suppression in comparison with control cultures (peripheral blood lymphocytes plus Trowell's T8 medium plus allogeneic cells or phytohemagglutinin but without supernatant). Each value is the mean ± SD of three replications.

phocytes suspensions from two unrelated volunteers were added in equal proportions (70 μl) to U-bottomed 96-well microculture plates (Corning Glass Works, Corning, New York) at a cell density of 2×10^5/well. The stored supernatants (from 48-hour culture) and control culture medium were thawed, sterilized by passing through a 0.22 μm Millex-GV filter unit (Millipore Co., Bedford, Massachusetts) just before use, and added to wells at a final concentration of 40% (vol/vol). Cultures were performed at 37° C in a humidified atmosphere of 5% carbon dioxide in air for 6 days, and 1 μCi of ^{3}H-thymidine (2 Ci/mmol, Amersham, Buckinghamshire, United Kingdom) was added to each well 20 to 24 hours before the end of the culture. The contents of each well were then harvested on filter papers with the use of a semiautomatic multiple cell harvester (Labo Science Co., Tokyo, Japan) and dried, and the radioactivity was counted in a liquid scintillation counter (Aloka Co., Tokyo, Japan) for 1 minute.

Phytohemagglutinin M–stimulation culture. Peripheral blood lymphocytes (1×10^6 cells/ml) and 10 μl/ml of phytohemagglutinin M (Difco Laboratories, Detroit, Michigan) were incubated in U-bottomed 96-well microculture plates at 37° C in a humidified atmosphere of 5% carbon dioxide in air. Preliminary experiments had shown that this dose of phytohemagglutinin M provided optimal lymphocyte responses under the same culture conditions. Supernatants or culture medium alone was added as described above to give a total volume of 250 μl/well. After 96 hours of culture including pulsation with 1 μCi/ml of tritiated thymidine for the final 6 to 8 hours, lymphocytes were harvested and counted as described above.

Viability of lymphocytes. The viability of lymphocytes at the end of mixed lymphocyte reaction and phytohemagglutinin M–stimulation cultures was >90% as assessed by trypan blue exclusion.

Calculation of results. All lymphocyte cultures were performed in triplicate, and the mean and standard deviation of the counts per minute (cpm) were calculated. Percent suppression compared with control cultures (peripheral blood lymphocytes + Trowell's T8 medium + phytohemagglutinin M or allogeneic cells but without supernatant) was calculated according to the formula:

$$\% \text{ Suppression} = \left(1 - \frac{\text{cpm in cultures with supernatant}}{\text{cpm in control cultures}}\right) \times 100$$

Statistical significance was examined by paired Student's *t* test.

Results

Effect of supernatants on mixed lymphocyte reaction. As seen in Fig. 1 and Table I, the mixed lymphocyte reaction was significantly suppressed by the addition of both secretory phase endometria (all 13 cases) and proliferative phase endometria (12 of 13 cases) as compared with control cultures ($p < 0.001$ and $p < 0.005$, respectively), with the suppressive activity of secretory phase endometria (mean 50% ± 19%) higher than that of proliferative phase endometria (mean 33% ± 36%). Most of the proliferative phase endometria samples (12 cases) were obtained from the late proliferative phase (cycle day 15 ± 2) and showed a mean suppression of 35% ± 37%. In contrast, one proliferative phase endometria sample from the early phase (cycle day 7) showed no significant suppressive effect, indicating that the suppressive activity gradually increased as the cycle progressed. On the other hand, supernatants of peritoneum and omentum had no sup-

pressive effect, while eight of 11 cases of tubal supernatants showed significant suppression when compared with the control cultures ($p < 0.025$).

The degree of suppression caused by endometrial supernatant was dose related. As shown in Fig. 2, suppressive activity increased as the concentration of secretory phase endometria increased, and at a final concentration of 60% (vol/vol) the lymphocyte response was completely abolished. Fig. 3 shows a dose-dependent curve with a constant concentration of secretory phase endometria (40% vol/vol) with decreasing cell numbers. The suppressive activity was progressively accentuated by decreasing the numbers of cells.

Experiments in which saline solution instead of supernatant was added were also carried out to determine whether the culture supernatants were depleted of nutrients. As shown in Fig. 1 and Table I, lymphocyte responsiveness was significantly ($p < 0.02$) reduced by the addition of saline solution (40% vol/vol of final concentration), with a mean suppression of 15% ± 10% as compared with control cultures. However, the suppressive activity of both secretory and proliferative phase endometria was still significantly greater than that of the saline solution ($p < 0.02$ and $p < 0.05$, respectively). The supernatants obtained from other tissues, including fallopian tubes, caused no significant suppression in comparison with the group that received saline solution.

Effect of supernatants on phytohemagglutinin M-induced lymphocyte reactivity. Both secretory (all 17 cases) and proliferative (10 of 11 cases) phase samples showed significant suppressive effects on phytohemagglutinin M–induced lymphocyte proliferation as compared with control cultures ($p < 0.001$ and $p < 0.005$, respectively; Fig. 4; Table II). The mean suppression of lymphoproliferation was higher in secretory phase endometria (60% ± 17%) than in proliferative phase endometria (45% ± 26%), but the difference was not statistically significant. One proliferative phase endometria sample from the early phase (cycle day 7) showed no significant suppressive effect, and other 10 proliferative phase endometria samples from the late phase (cycle day 15 ± 3) showed significant suppression ($p < 0.025$). The inhibitory effect was dose dependent, similar to that seen in mixed lymphocyte reaction experiments (Fig. 2, *B*). In contrast, the supernatants obtained from omentum (13 cases) showed no suppression, but supernatants from fallopian tubes (seven cases) showed significant suppression in comparison with control cultures ($p < 0.05$). The addition of saline solution to phytohemagglutinin M–stimulation culture showed significant inhibition

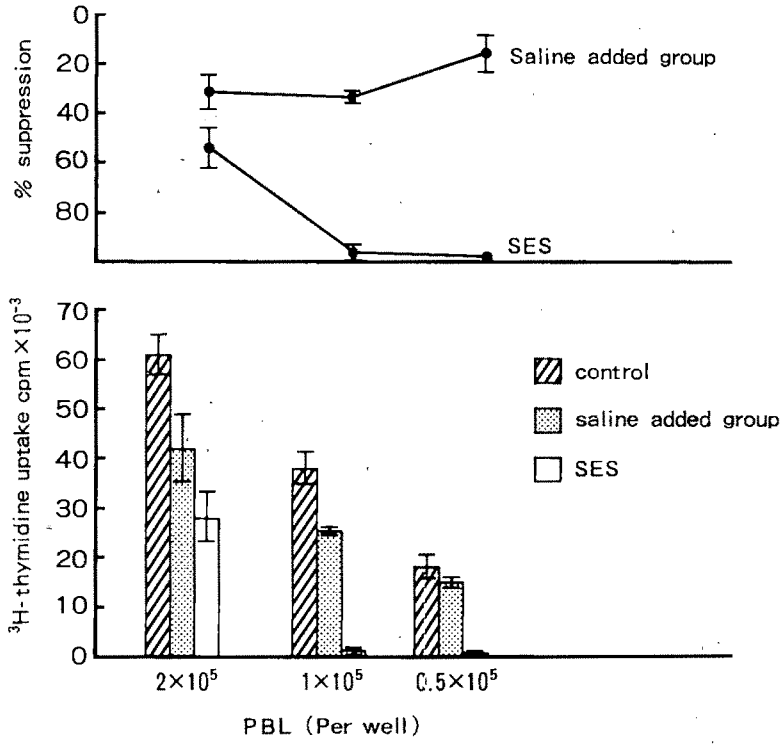

Fig. 3. Dose-dependent suppression of secretory phase endometria *(SES)* of mixed lymphocyte reaction. Each well contained a constant volume of secretory phase endometria (40%) with varying concentrations of peripheral blood lymphocytes *(PBL)*. Results are expressed as percent suppression in comparison with control cultures (peripheral blood lymphocytes plus Trowell's T8 medium plus allogeneic cells but without supernatant) and as counts per minute. Each value is the mean ± SD of three replications.

(mean 12% ± 13%) as compared with control cultures ($p < 0.05$). However, the levels of suppression caused by secretory and proliferative phase endometria were still significantly higher than that of the saline solution group ($p < 0.001$ and $p < 0.005$, respectively). On the other hand, the supernatants from fallopian tubes and omentum showed no significant suppression when compared with the saline solution group (Fig. 4; Table II).

In other experiments, serial dilutions of phytohemagglutinin M were added to the cultures (final concentration 10, 20, and 40 μl/ml) with a constant dose of endometrial supernatants. As shown in Fig. 5, the activation of lymphocytes was stimulated by phytohemagglutinin M, but increased concentrations of phytohemagglutinin M did not further enhance the reactivity of lymphocytes.

Effect of duration of endometrial culture. Supernatants were removed from cultures of human endometria at the times indicated (from 12, 24, 48, and 72 hours) and were tested. Endometrial supernatants from 12-hour culture had little or no suppressive effect on lymphocyte reactivity to phytohemagglutinin M and the mixed lymphocyte reaction (Fig. 6). The levels of suppression were progressively accentuated by increasing the culture times, and were maximum at 48 hours. However, a further 24-hour culture (total 72 hours) had no additional effect, suggesting that the major portion of the suppressive factor(s) was released 48 hours after the start of culture.

Comment

Our present study demonstrates that the supernatants obtained from explant cultures of both proliferative and secretory phase endometria showed marked suppression of the unrelated adult lymphocyte response to phytohemagglutinin M stimulation and the mixed lymphocyte reaction. The suppression of lymphoproliferation by the supernatant of secretory phase endometrium was higher than that of the proliferative phase sample in both mixed lymphocyte reaction- and phytohemagglutinin M-mediated cultures. The inhibitory effect of endometrial supernatant was dose related, nonspecific, and more likely due to the presence of suppressive factor(s) rather than the nutritional depletion, because under poor nutritional culture conditions, the lymphocyte reactivity was enhanced by decreasing the cell numbers (as seen in the group that

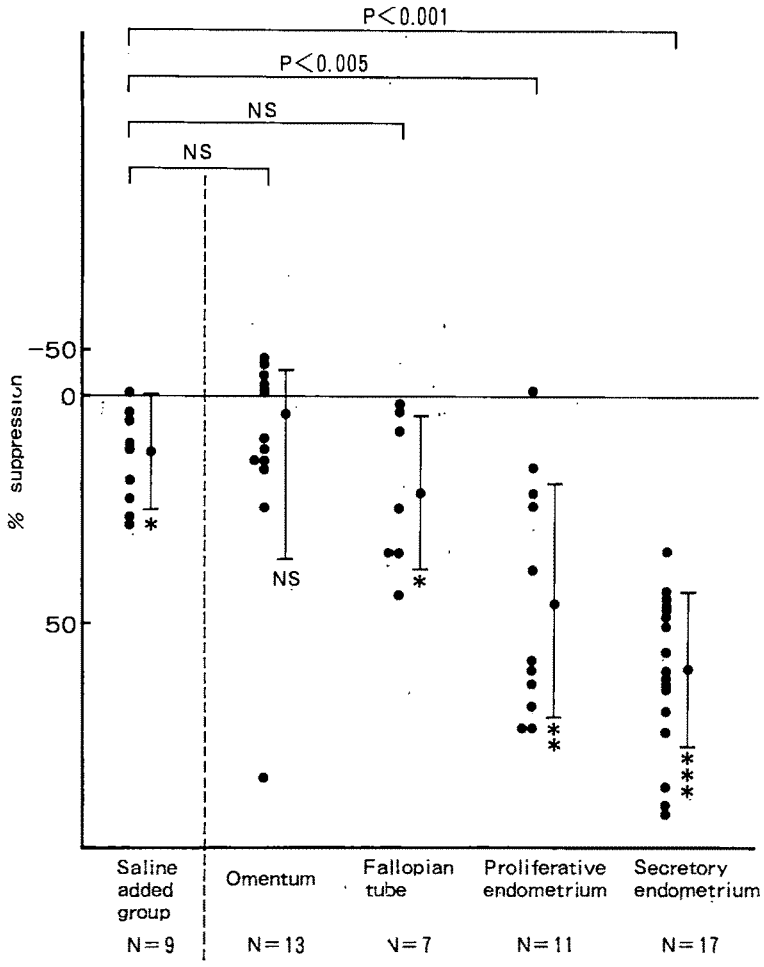

Fig. 4. Effect of tissue culture supernatants on phytohemagglutinin-mediated lymphocyte reactivity. Results are expressed as percent suppression in relation to control cultures (peripheral blood lymphocytes plus Trowell's T8 medium plus phytohemagglutinin but without supernatant). Each *point* represents the mean percent suppression of triplicate incubations, and *vertical bars* represent the mean ± SD of each group. Statistical significance was calculated by paired Student's *t* test as follows: * = $p < 0.05$; ** = $p < 0.01$; *** = $p < 0.001$; NS = not significant.

had saline solution added [Fig. 3]). In the presence of endometrial supernatant, however, lymphocyte proliferation was progressively inhibited by decreasing the cell numbers. Supernatants obtained from the omentum and peritoneum had no suppressive activity. Supernatants from fallopian tubes showed some suppressive activity in comparison with control medium (Trowell's T8 medium), but the level of inhibition was similar to that in the saline solution group. These results suggest that human endometrium releases a soluble suppressive factor that is capable of afferent blockade of the immune response, as the mixed lymphocyte reaction is considered an in vitro analogue of the afferent arm of immune response.

The highest values of progesterone concentrations in both secretory and proliferative phase endometria samples were 3 and 0.5 ng/ml, respectively. These concentrations were too low to inhibit immune reactivity, because several reports[9] and our preliminary study revealed that the minimum effective concentration of progesterone for such suppression was in the range of micrograms. The suppressive effects of mixed lymphocyte reaction– and phytohemagglutinin M-induced lymphocyte reactivity were not due to cytotoxicity of the endometrial tissue culture supernatants, because the viability of lymphocytes cocultured with endometrial supernatants was usually >90%. The possibility that the inhibitory effects were caused by a complex reaction between endometrial supernatants and phytohemagglutinin M, thus making it unavailable for cell transformation, is not likely because the lymphocyte response could not be enhanced by increasing concentrations of phytohemagglutinin M with the constant dose of endometrial supernatants.

The immunologic characteristics of endometrial secretion are of considerable interest because sperm mi-

gration and blastocyst transport to the site of implantation occur in this fluid. Recently, many hormone-dependent substances were reported to be released from the endometrium,[4] but very little is known about their immunologic character. Tourville et al.[5] observed a strong IgG staining in the human endometrium, particularly during the secretory phase, and Menge and Lieberman[6] found that rabbit uterine fluid contained both IgG and IgA. Furthermore, lymphoid aggregates are found in the endometrial mucosa during the menstrual cycle.[7] Head and Seelig[8] showed that typical lymphatic vessels are present in the rat endometrium. Moreover, hormone-dependent large lymphoid cells, which suppress mitogen-induced lymphocyte reactivity, have been isolated from the human endometrium in the luteal phase.[9] These findings raise the possibility that the endometrium has a local immunoregulatory function.

During the last several years, some investigators have suggested that decidual tissue could fulfill a role in protecting the fetus from the maternal immune response by releasing some soluble immunosuppressive factor.[1,2] However, it is still unsettled whether the factor is already present in the endometrium before implantation or if some newly developed cells release it, as the possible bone marrow origins of some decidual cell precursors have been reported recently.[10] Our results indicate that the human nondecidualized endometrium contains a soluble suppressive factor involved in cell-mediated immunity and that the production of the factor increases as the menstrual cycle progresses.

The high frequency of early embryonic loss before implantation[11] and the low success rate of in vitro fertilization and embryo transfer in the human may be explained in part by the lack of some suppressive factor(s) in the endometrium. Elucidation of the mechanism of cellular and molecular events involved in the production or/and release of the factor(s) from human endometrium might shed light on a way to improve the treatment of infertility caused by implantation impediment.

Magnesium and zinc status during the menstrual cycle

Patricia A. Deuster, Ph.D., Eran Dolev, M.D., Lani L. Bernier, B.S., and Ulrike H. Trostmann, M.S.

Bethesda, Maryland

The effect of menstrual cycle phases on the indexes of magnesium and zinc status was assessed in five normally menstruating women. Plasma concentrations of magnesium and zinc and the magnesium and zinc content of red blood cells and peripheral blood mononuclear cells were measured for 3 or 5 days per week during three menstrual cycles. The cycles were divided into four phases: menses, follicular, ovulatory, and luteal. Plasma magnesium concentrations were highest during menses and then gradually declinec, reaching the lowest point during the ovulatory phase. This was followed by a rise during the luteal phase. Plasma zinc concentrations were higher during menses and the follicular phase and then dropped during the ovulatory and luteal phases. Both the magnesium and zinc content of red blood cells and mononuclear cells remained constant over the course of the study and did not change significantly as a function of cycle phase. This study provides evidence that plasma magnesium and zinc concentrations fluctuate during the menstrual cycle in a phase-related fashion in normally menstruating women. Whether these changes are hormonally mediated or reflect metabolic changes will require further study. (AM J OBSTET GYNECOL 1987;157:964-8.)

Key words: Compartmentalization, follicular, luteal, menses, mononuclear cell, ovulation, red blood cell

The menstrual cycle is the result of complex interacting processes within the hypothalamus, the hypophysis, the ovaries, and the uterus.[1] Many changes occur within each of these different systems during the normal cycle, with each change dependent on a variety of sensitive regulatory mechanisms. Hormonal changes within each phase of the cycle have been well documented, but there is still uncertainty about specific mediators and regulators of the hormonal changes.

There is evidence that certain essential minerals may serve physiologic roles in regulating the release and/or biologic activity of hormones and neuropeptides involved in the menstrual cycle.[2-4] For example, zinc has been found to be involved in the regulation of progesterone[2] and prolactin activity.[3] In addition, recent data indicate that zinc ions may serve a critical role in endogenous opiate-receptor binding in the central nervous system.[4] Although no specific role has been assigned to magnesium in the regulation or maintenance of menstrual function, magnesium is involved in basal energy metabolism that changes over the course of the menstrual cycle.[5] Furthermore, it is believed that magnesium deficiency may be a possible cause for premenstrual tension syndrome.[6] This information suggests that distinct patterns in the distribution and/or metabolism of essential minerals might be observed during the menstrual cycle.

Patterns of change in the plasma concentrations of various minerals, such as calcium, phosphorous, magnesium, and zinc, across the menstrual cycle have been the subject of several research endeavors to delineate associations between hormonal changes and essential minerals.[7-10] However, the data are scarce, and whether there are clearly defined changes in the compartmentalization of these minerals has not been carefully studied. The purpose of this study was to evaluate changes in the plasma concentrations of magnesium and zinc as a function of menstrual cycle phase in healthy, normally menstruating women across three cycles. In addition, the magnesium and zinc content of red blood cells and peripheral blood mononuclear cells was measured to examine compartmental changes and yield more relevant information concerning the dynamics of magnesium and zinc metabolism during the menstrual cycle.

Material and methods

Informed consent was obtained from five healthy adult women, who ranged in age from 23 to 37 years, after they were instructed on the nature of the project. Three of the women were nulligravid, and two had two

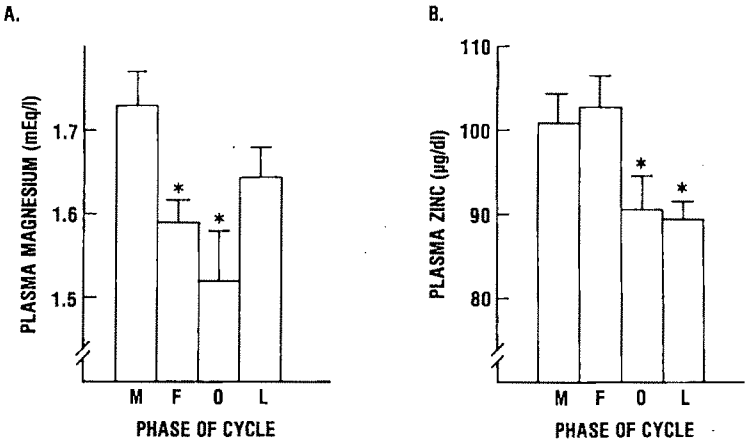

Fig. 1. Mean (±SEM) plasma concentrations of magnesium *(Panel A)* and zinc *(Panel B)* during menses *(M)*, the follicular *(F)*, ovulatory *(O)*, and luteal *(L)* phases of the menstrual cycle for five women. (*$p < 0.01$.)

and three previous term pregnancies, respectively. All had normal cycles, and none used any contraceptives or other medications. Furthermore, none suffered from premenstrual tension syndrome. The protocol had been approved by the Human Use Research Committee of the Uniformed Services University of the Health Sciences. Blood (25 ml) was drawn from an antecubital vein beginning on the first, second, or third day of the cycle (counting the onset of menses as day 1) at 8:00 AM after an overnight fast and collected 5 days a week until the onset of menses. The length of the menstrual cycle ranged from 24 to 31 days. By knowing the cycle length and basal body temperature, days within the menstrual cycle were classified into one of four phases: menses, follicular, ovulatory, and luteal. Values within each phase for each subject were grouped and averaged, and averages by phase were then calculated across subjects.

All blood samples were drawn into metal-free plastic syringes and transferred into three polypropylene tubes (Walter Sarstedt, Inc.; Princeton, N.J.): (1) no anticoagulant for whole blood measurements of magnesium and zinc concentrations and subsequent calculation of magnesium and zinc content of red blood cells, (2) ethylenediaminetetraacetic acid for complete blood cell counts, and (3) heparin for plasma concentrations of albumin, magnesium, and zinc and separation of mononuclear cells for magnesium and zinc content. Samples were processed immediately and any sample undergoing hemolysis was discarded.

Biochemical analyses. Red and white blood cell counts were determined on a Coulter counter Model ZM, and blood hemoglobin was measured with a Coulter Electronics hemoglobinometer. Hematocrit was determined in triplicate in microcapillary tubes centrifuged for 5 minutes at 12,000 rpm. Whole blood was hemolyzed by dilution with deionized water, vortexed, and then frozen for later analysis. Plasma from heparinized tubes was separated from whole blood by centrifugation and frozen for later analysis. Peripheral blood mononuclear cells were isolated from heparinized blood by the procedure of Elin and Hosseini.[11] In brief, this procedure involves the separation of mononuclear cells by centrifugation with an aqueous solution of sodium diatrizoate and Ficoll (Isolymph, Gallard-Schlesinger Chemical Mfg. Corp., Carle Place, New York), harvesting, and counting the cells, which is followed by lysing the cells with deionized water and ultrasonication to release magnesium and zinc. Differential counts were performed on cytocentrifuge smears of harvested cells to document the percentage of mononuclear cells (>95). The magnesium and zinc concentrations in all samples were measured by atomic absorption spectrophotometry (Model 603, Perkin-Elmer, Eden Prairie, Minn.). Plasma albumin was measured on radial immunodiffusion plates with kits (Behring Diagnostics, La Jolla, Calif.). All tubes, containers, and reagents were carefully checked for contamination. Standard errors of measurement were less than 3% for all assays with the exception of the magnesium and zinc content of mononuclear cells, with standard errors of measurement of 6.8% and 7.5%, respectively.

Calculations. Magnesium and zinc content of red blood cells was expressed as nanograms per 10^6 cells and calculated as follows: (Whole blood concentration − plasma concentration × [(100 − HCT)/100])/RBC count where HCT is hematocrit and RBC is red blood cell. The magnesium and zinc content of mononuclear cells was also expressed as nanograms per 10^6 cells and calculated as lysate concentration/lysate cell count.

Statistical analyses. All data were analyzed by anal-

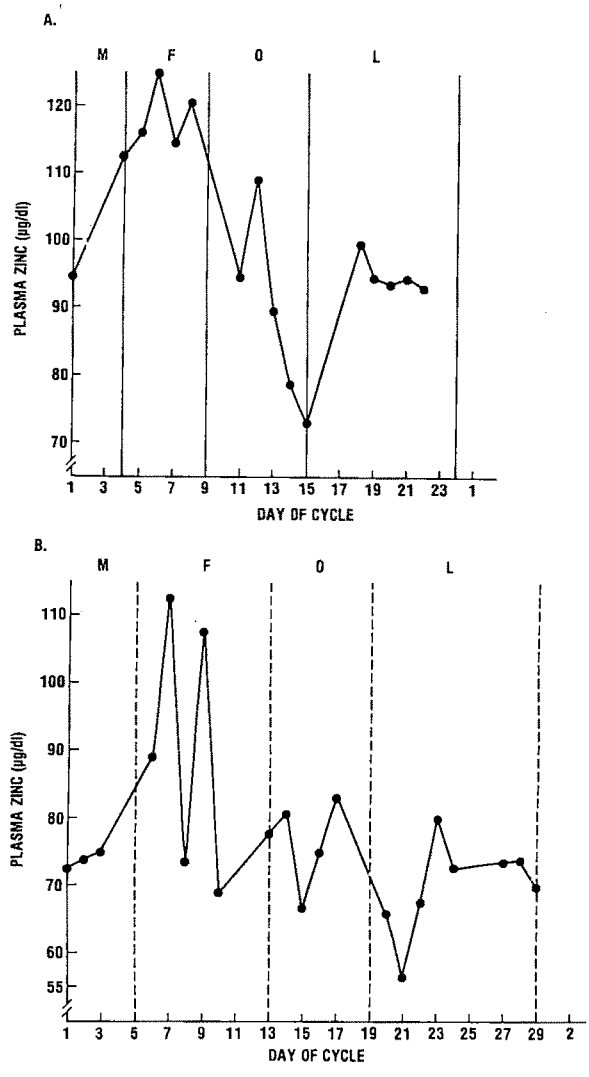

Fig. 2. Plasma zinc concentrations during the course of the menstrual cycle for two women with cycle lengths of 24 days *(Panel A)* and 29 days *(Panel B)*. (*M* = Menses; *F* = follicular; *O* = ovulatory; *L* = luteal.)

ysis of variance procedures to determine differences as a function of the four menstrual phases. When a significant effect was noted, Duncan's multiple range test was used. Standard correlation and regression procedures were used to assess interrelations between variables. The null hypothesis was rejected when $p < 0.05$.

Results

Mean plasma concentrations of magnesium and zinc for the subjects as a function of the four phases of the menstrual cycle are summarized in Fig. 1, *A* and *B*. There were significant differences in mean concentrations of both plasma magnesium and zinc across the four phases. Plasma magnesium concentrations varied in all subjects from day to day, but the values were highest during menses and then gradually dropped, reaching a low point during the ovulatory phase. During the luteal phase, plasma magnesium concentration began to rise.

Mean plasma concentration of zinc was highest during menses and the follicular phase and then dropped significantly during the ovulatory and luteal phases. Plasma zinc concentration tended to vary markedly during the follicular and ovulatory phases, and precipitous drops of 20 to 40 µg/dl were observed during these phases. The drops usually occurred within a 1-day period, between days 14 and 21, depending on cycle length. Patterns of change for two of the subjects with cycle lengths of 24 and 29 days are depicted in Fig. 2, *A* and B, respectively. As indicated, during the luteal phase, plasma zinc concentration was less variable than during the follicular or ovulatory phases. Although plasma albumin levels also varied considerably, with changes of up to 1.4 gm/dl noted across the cycle, the direction and magnitude of change did not always parallel that for plasma magnesium or zinc. However, the greatest declines were noted during the ovulatory phase.

The magnesium and zinc content of red blood cells and mononuclear cells exhibited considerably less day-to-day variation over the course of the menstrual cycle (Table I), and no significant patterns in these intracellular compartments were detected. When the magnesium and zinc content of red bloods was expressed relative to liters of blood hemoglobin, similar results were noted.

Comment

During the past several years, there has been increasing interest in the relationship between the metabolism of essential minerals and the regulation of hormone release and activity. Although the coordinated sequence of hormonal changes during the normal menstrual cycle is well characterized, whether similar or parallel changes occur in the distribution of selected minerals has not been clearly established. The results of this study provide preliminary evidence that there are specific phase-related patterns for plasma magnesium and zinc during the menstrual cycle despite marked day-to-day variation. In contrast, the content of magnesium and zinc in red blood cells and mononuclear cells remained relatively constant throughout the cycle.

Several studies have provided evidence for phase-related changes in blood constituents during the menstrual cycle,[7-10, 12] but various compartmental changes in magnesium and zinc have not been previously studied. The present study revealed that distinct changes occur in plasma magnesium during the menstrual cycle, with the lowest levels occurring during the ovulatory phase. This is consistent with the findings of Piffaretti[12] but not with those of Pitkin et al.[7] and M'Buyamba-

Table I. Mean content of magnesium and zinc in red blood cells and peripheral blood mononuclear cells averaged within phases during the menstrual cycle for normally menstruating women

Kabangu et al.[10] These investigators reported no significant patterns in plasma magnesium across the menstrual cycle. However, careful inspection of the data of Pitkin et al. reveals a midcycle drop. Thus it appears that there is a phase-specific pattern for plasma magnesium.

Although changes in albumin level may affect plasma magnesium concentration since albumin is reported to bind 25% of plasma magnesium,[13] the observed changes in plasma magnesium were independent of albumin levels. Thus other interpretations are sought. One possibility is that changes in plasma magnesium concentration are related to changes in basal metabolic rate in that both occur during midcycle.[5] Alternatively, the decline may be due to increases in parathyroid hormone or aldosterone, both of which increase before ovulation[7, 10] and induce decreases in plasma magnesium concentration.[14] However, the mechanism or signal responsible for the drop remains to be determined.

Although there are reports that the magnesium content of red blood cells is reduced in women with premenstrual tension syndrome, to the best of our knowledge no studies have examined patterns of change in the magnesium content of red blood cells or mononuclear cells during the menstrual cycle. The findings in the present study of no significant change in the magnesium content of either red blood cells or mononuclear cells provide evidence that the metabolism and distribution of magnesium in these tissues are probably independent of cycle phase in women with normal menstrual cycles. The data do not, however, rule out the possibility that a disturbance or abnormality in menstrual function might alter magnesium homeostasis. Conversely, whether a disruption in the metabolism or redistribution of magnesium contributes to the severity and/or onset of premenstrual tension syndrome remains to be determined.

The role of zinc in the reproductive function of women remains obscure, although several theories have been proposed. A relationship between zinc and progesterone binding[2] and zinc and prolactin release[3] has been proposed. Furthermore, there is evidence to suggest that zinc is an important modulator of opiate-receptor binding,[4] and endogenous opioid peptides participate in the control of gonadotropin secretion.[1] Thus there are several mechanisms whereby zinc might serve to regulate events in the menstrual cycle.

Patterns of change in plasma concentration of zinc have been previously reported,[9, 10] with peak values observed at ovulation. However, inspection of earlier data revealed minimal day-to-day variation. The results of this study also provide evidence for distinct patterns in plasma zinc concentration, but we found marked day-to-day variability. The pattern observed in this study was characterized by high mean plasma concentrations of zinc during menses and the follicular phase, followed by a decline to significantly lower levels during the ovulatory and luteal phases. Sharp rises and falls were noted during the late follicular and ovulatory phases, whereas during the luteal phase, plasma levels were remarkably stable.

Reasons for the observed changes in plasma zinc during the menstrual cycle are uncertain, but one might postulate that the sharp changes in plasma zinc may be related to hormonal changes or changes in the distribution of specific carrier proteins. Although albumin is the predominant carrier, binding 70% to 85% of zinc in plasma,[15] the differences observed in the present study could not be explained by variations in plasma albumin. Thus other explanations must be offered. For example, marked variations in plasma zinc concentration may be required to regulate the activity or binding of selected hormones.[2, 3] The precipitous decline during the ovulatory phase and the maintenance of low concentrations during the luteal phase may also be related to estrogen levels.[15] Alternatively, recent studies have provided evidence that plasma interleukin-1, which is associated with a reduction in plasma zinc,[15] is elevated during the luteal phase.[16] Thus interleukin-1 may be a regulator of zinc during the menstrual cycle. Finally, the low concentration of plasma zinc observed in this study during the luteal phase complements the results of Hag-

enfeldt et al.,[17] who reported higher levels of endometrial zinc during the luteal phase compared with the follicular phase. Zinc may be preferentially removed from plasma and taken up by endometrial tissue during the luteal phase to regulate progesterone and estradiol binding to tissue receptors. However, further studies will be required to address these particular issues.

No previous studies have explored potential interactions between intracellular zinc content and phases of the menstrual cycle. As was observed with intracellular magnesium, there were no particular patterns of change in the zinc content of red blood cells or mononuclear cells. There was day-to-day variation, but no distinct patterns as a function of cycle phase emerged. Because the intracellular zinc content of these specialized cells is not regulated by reproductive hormones, these tissues may provide a better reflection of actual zinc status.

In summary, the results of the present study provided evidence that the magnesium and zinc content of red blood cells and mononuclear cells does not change over the course of the menstrual cycle. In contrast, changes in plasma magnesium and zinc concentrations were noted. For plasma magnesium there was a gradual decline from menses to the ovulatory phase, followed by a rise during the luteal phase. Phase-related patterns in plasma zinc concentration were characterized by higher concentrations during menses and the follicular phase, followed by a decline during the ovulatory and luteal phases. Significant day-to-day variation was noted for both cations. Whether these changes are strictly an epiphenomenon resulting from hormonal changes or whether there is a deliberate redistribution of magnesium and zinc from plasma to other tissues wherein they serve regulatory functions is unknown. Future investigations will be required to answer these questions.

Partial hydatidiform moles: Deoxyribonucleic acid content and course

John R. Davis, M.D., Daniel P. Kerrigan, M.D., Dennis L. Way, B.S., and Sheldon A. Weiner, M.D.

Tucson, Arizona

Partial moles are either diploid (46 chromosomes) or triploid (69 chromosomes). In 35 cases ploidy was measured by flow cytometry for nuclear deoxyribonucleic acid quantitation, indicating approximate chromosome number. Six of the 35 were triploid (17%) and the balance was diploid (83%). No complications occurred in the triploid group, while five of 25 (20%) diploid cases with evaluable follow-up had nonfatal sequelae. Complications included persistent mole treated by recurettage and four cases requiring chemotherapy (human chorionic gonadotropin titer plateau, clinical metastasis, overt choriocarcinoma, and placental site trophoblastic tumor). A combined morphologic and genetic classification of partial moles is recommended for identification and risk assessment. Deoxyribonucleic acid cell cycle fractions of the diploid partial moles may be helpful in the identification of patients at high risk for complications. A proliferation index >3.6 separated the cases with sequelae from most of the uncomplicated cases (sensitivity 100%, specificity 95%). (Am J Obstet Gynecol 1987;157:969-73.)

Key words: Partial mole, deoxyribonucleic acid content, chromosomal analysis

Makino et al.[1] in 1964 were the first to associate triploidy (69 chromosomes) with a placental mole of distinctive "transitional" structure. In 1976 two groups defined two molar entities as complete and partial. Vassilakos et al.[2] indicated that a slight majority of partial moles was diploid (46 chromosomes) and free of sequelae, whether triploid or not. Conversely, Stone and Bagshawe[3] reported that five of 189 partial moles (classified by morphologic criteria) required therapy for human chorionic gonadotropin titer persistence or clinical metastases. Since then there has been disagreement regarding the classification of partial moles (with morphologic criteria alone or an emphasis on cytogenetics) and the incidence of postmolar complications. Szulman and Surti[4] recognized partial moles typically as triploid and noted a low rate of sequelae in their series (two of 49). Lawler et al.[5] encountered only triploid partial moles, with no sequelae (15 cases, eight successfully karyotyped). Ohama et al.[6] reported 47 triploid cases and 9 diploid, with no complications. Series of partial moles diagnosed solely by morphologic criteria[7-9] show a higher complication rate (six of 83 total cases required treatment). Cases reported by Teng and Ballon[10] indicated two of three nontriploid partial mole cases required treatment, and an invasive mole was reported after a triploid partial mole by Gaber et al.[11]

Two pertinent questions arise: How frequent are diploid partial moles, and is there a risk difference between the two types of partial mole? Partial moles from our hospital were reviewed, their deoxyribonucleic acid (DNA) content was measured in tissue retrieved from paraffin blocks, and the clinical course of the patients was assessed. DNA quantitation was performed by flow cytometry, which allows approximate correlation with chromosome numbers. The sensitivity of the technique is sufficient to distinguish diploidy from triploidy, although differences of a few small chromosomes cannot be resolved.

Material and methods

Of the thirty-five cases of partial mole, all were retrieved from our surgical pathology files since 1981, except for one 1976 case previously karyotyped as triploid. Specimens were from curettage procedures, except for one in which hysterectomy was the primary treatment and one that involved salpingectomy for ectopic tubal pregnancy. Histopathologic review excluded both complete hydatidiform mole and hydropic abortion. The criteria of Szulman and Surti,[12] including fetal presence, placental membranes, villous vasculature, and partial villous involvement (normal and edematous villi), served to exclude a diagnosis of complete mole; criteria of trophoblastic hyperplasia (greater than normal for gestational age) and partial villous involvement eliminated hydropic abortion. In some instances the

*Hysterectomy without curettage.

clinical features of the mole further distinguished partial moles from abortions. Selected first trimester elective abortions were used as controls for the identification of trophoblastic hyperplasia. Medical records were reviewed for clinical presentation, gestational age, serum human chorionic gonadotropin titers, and follow-up.

The size of villous vesicles was recorded from gross specimen descriptions if available, or was measured from tissue sections. The degree of trophoblastic hyperplasia was recorded on a scale of 1 to 4 by selecting and grading the most intense hyperplasia prevalent in a low-power microscopic field (4.5 mm).

For DNA quantitation, representative samples were retrieved from paraffin blocks and prepared for flow cytometry according to the method of Schutte et al.[13] We introduced further disaggregation modifications that provided enhancement of DNA histograms. Briefly, the method involves manual slicing of thick sections from paraffin blocks with a scalpel to include chorionic villi with trophoblasts and maternal tissue for internal control, with sampling guided by a hematoxylin-eosin–stained section. Dewaxing in xylene and rehydration are standard. Our method included mincing slices with crossed scalpels followed by a novel enzymatic disaggregation. The sample was incubated at 37° C for 36 to 48 hours in 0.2% trypsin and 0.1% ethylenediaminetetracetic acid in phosphate-buffered saline solution A with 200 U/ml collagenase IV. Subsequent gentle syringing with 18- to 26-gauge needles,

filtration through a 30 μm nylon mesh, and washing provided enhanced harvests of cell suspensions. Staining was performed for 30 minutes at room temperature with ribonuclease (to eliminate ribonucleic acid), 1% NP40 (detergent), and propidium iodide (a DNA stain). With these added disaggregation methods, DNA histograms with coefficients of variation (sharpness of histogram peaks) <5% were considered good (EPICS V argon laser flow cytometer). Usually 10^4 nuclei were measured for DNA content in each case.

In addition to maternal tissue for an internal DNA quantitation control, an external control of paraffin-retrieved normal secretory endometrium was used for standardization of the histograms. The major objective was to classify partial moles as diploid or triploid. Cell cycle components were calculated from the histograms by PARA 1 analysis, a mathematic program for estimating cell proliferation characteristics. In Fig. 1 the histogram on the right has a normal diploid pattern; the 2n peak is the GO-1 diploid cell cycle fraction (nonreplicating chromosomes in modal range 46), the S fraction is the synthetic phase of chromosomes replicating DNA, and the 4n peak is the G2-M tetraploid fraction of fully replicated chromosomes before or at mitosis. The percentages are an imperfect representation of trophoblastic proliferation because GO-1 maternal and villous stromal cells were included, but sample parity allows rough comparison of S and G2-M fractions. Clinical, morphologic, and DNA quantitation data are listed in Table I. Five nonmolar abortions were used for trophoblast proliferation controls.

Table II. Proliferation index in diploid partial moles

Index	Complications	No complications
>3.6	4	1
<3.6	0	18
	4	19

Nonevaluable cases included Nos. 9, 30, and 34 (unanalyzable cell cycle fractions), 16 and 35 (lack of follow-up), and 15 (initial hysterectomy).

Results

Of the 35 cases, six were triploid (17%) and 29 were diploid (83%). Two cases (Nos. 1 and 3) of triploidy were confirmed by prior karyotyping. Only two cases in the diploid group were karyotyped. Case 8 was 46,XX; since parental karyotypes were not examined, the origin of the genome could not be evaluated (normal fertilization or androgenetic). Case 28 was trisomic 47,XX,+20; aneuploidy was too small to be detected by flow cytometry.

No complications occurred in the triploid group. Excluding four cases (Nos. 15, 16, 34, and 35) with nonevaluable follow-up, five of 25 (20%) diploid cases had sequelae. The sequelae were human chorionic gonadotropin titer plateau (case 7), plateau with clinical lung metastases (case 8), persistent mole (case 9), morphologically proved choriocarcinoma (case 10), and an aggressive placental site trophoblastic tumor (case 11). All five required chemotherapy, except case 9, which underwent recurettage. No fatalities have occurred. The human chorionic gonadotropin titers were negative at the designated follow-up in the nonsequelae cases (except case 2, which was lost to follow-up; Table I).

Abortion controls included a nonmolar case with DNA content in the triploid range, but with trophoblastic atrophy. Other controls were either nonevaluable for DNA content due to hypocellularity or were diploid with low proliferative characteristics.

Except for the proliferation index, no significant rela-

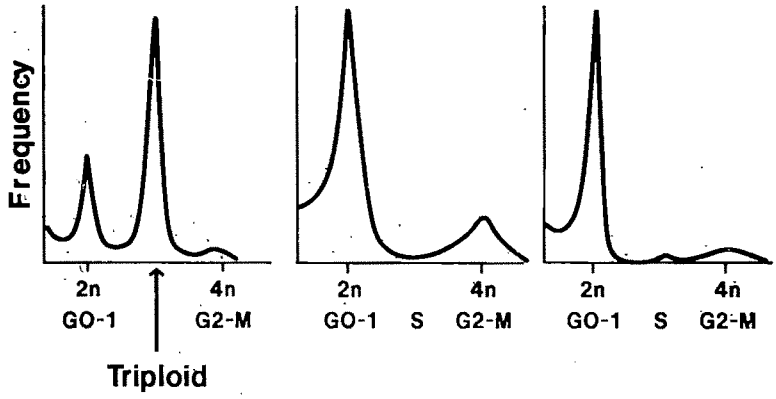

Fig. 1. Examples of DNA histograms. The y axis represents the number of nuclei measured; the x axis is fluorescence intensity representing DNA quantity in nuclei; 2n is within the diploid range of chromosomes (GO-1 cell cycle fraction); 4n is tetraploid range (G2-M fraction); and synthetic S fraction occurs at low levels in between. The first case (No. 1) is triploid *(arrow)*; the 2n and 4n peaks are internal control standards. The middle histogram is case 15, with a diploid pattern and high proliferation index (67.5). The last case (No. 12) is also diploid, with a low proliferation index (2.2).

tionships were present among the factors listed in Table I. However, as trends, the diploid cases with sequelae differed from triploid and diploid without sequelae in greater frequency of clinical mole presentation, <10 weeks' gestational age, trophoblastic hyperplasia ≥2+, human chorionic gonadotropin titer >20,000 mIU/ml serum, GO-1 ≤65%, and S phase ≥14%.

Because the complication cases had high G2-M cell cycle fractions, a proliferation index (PI) was calculated as: PI = $(G2\text{-}M)^2/GO\text{-}1$ (Tables I and II). All four evaluable complication cases and only one of 19 uncomplicated diploid cases ($p < 0.001$) had a proliferation index >3.6 (100% sensitivity and 95% specificity). The predictive value of this index was 80% positive and 100% negative. Fig. 1 includes diploid histograms with high and low proliferation indices.

Comment

Ascertainment of a partial mole has been a problem. Series of partial moles with follow-up information have either emphasized triploidy or were based on morphologic classification without cytogenetics (Table III). Cases classified cytogenetically[2, 4-6] included two of 156 (1.3%) requiring treatment, while in the cases classified morphologically[2-5, 7-9] 11 of 297 (3.7%) were treated for sequelae. Our combined DNA and morphologic approach should help to clarify questions of incidence and risk subsets of partial mole.

The true incidence of partial mole can be determined not only by distinguishing partial mole from complete mole, but partial mole from hydropic abortion. Only 10 of our cases were clinically moles, and nine had gross vesicles ≥5mm. Microscopic evaluation is necessary to

identify cases with microvesiculation. Perhaps more critical in partial mole recognition is differentiation from hydropic abortion. Our criteria stress trophoblastic hyperplasia for dates and partial villous involvement. To insist on a level of vesicle size would not allow recognition of early stages of molar development. Regardless of diagnosis of mole, all abortions with trophoblastic hyperplasia in our hospital are followed by human chorionic gonadotropin titer analysis. Careful scrutiny of "abortions" will yield cases of early partial mole. This raises speculation that some of the estimated 25% abortion antecedents for choriocarcinoma are unrecognized early moles (partial or complete).

Because complete moles and some partial moles are 46,XX, karyotypes alone may not be discriminatory. The androgenetic origin of complete moles is characteristic, although other fertilization mechanisms occasionally occur and may lead to confusion with partial mole cytogenetic patterns.[14] Morphologic criteria for classification of the two types of mole are well established; in partial mole there is evidence of fetal presence (gestational sac membranes and fetal vasculature with nucleated erythrocytes) and partial involvement (normal and vesicular villi). Although the two moles appear distinctive in origin, theoretically partial mole in advanced developmental stages could lose distinguishing features and simulate complete mole.

Our results more firmly establish that partial moles consist of triploid and diploid subsets, as others have suggested.[2, 15] Triploid partial moles are at low risk for sequelae, while diploid partial moles are at moderate risk. Our incidence of 20% sequelae is greater than the 15% accepted for complete moles, but is probably influenced by an ascertainment bias of cases 10 and 11. In both we encountered the sequelae before studying the antecedent mole. If these two cases are dismissed, the complication rate in the diploid group is three of 23 (13%). Further studies are needed to validate the risk level.

DNA quantitation of moles by flow cytometry is an easy, rapid method applicable to retrospective studies. It can also be used with fresh tissue as an alternative to cytogenetics. If morphologic features are the basis of partial mole diagnosis, DNA ploidy can serve to separate mole subsets without bias. A combination of chromosomal (or DNA) and morphologic evaluation is required for accurate assessment of biologic potential in molar disease.

A trophoblastic proliferation index >3.6 was arbitrarily selected as a characteristic of diploid partial moles with sequelae. This value was exceeded in only one of 19 uncomplicated diploid cases and two of six triploid cases. The role of the index as a risk factor requires further study.

Correlation between chlamydia infection and clinical evaluation, vaginal wet smear, and cervical swab test in female adolescents

Henning Thejls, M.D., Vivi Anne Rahm, Gerd Rosen, and Håkan Gnarpe, M.D., Ph.D.
Gävle, Sweden

Vaginal wet smear, endocervical swab test, gynecologic examination, and history were investigated in 148 healthy female adolescents. Cultures for *Chlamydia trachomatis* were obtained from all patients. The overall prevalence was 19/148 (13%). No significant correlation was found between chlamydia infection and any of the parameters investigated in the wet smear. Results of swab test or history showed no discrimination between young women with cultures positive for *C. trachomatis* and those with cultures negative for *C. trachomatis*. Chlamydia was found in 32% of patients when the gynecologic examination showed signs of infection and in 10% when no signs of infection were seen ($p < 0.025$). Thirteen of the 19 (70%) adolescents with chlamydia infections had no signs of infection. We conclude that neither swab test, vaginal wet smear, nor the history of the patient can give conclusive evidence of a chlamydial infection. Detection of *C. trachomatis* in this population can be done only by culture or other specific methods. (Am J Obstet Gynecol 1987;157:974-6.)

Key words: *Chlamydia trachomatis*, chlamydial infections, female adolescents

Chlamydia trachomatis is a major pathogen in genital infections that may cause serious complications such as salpingitis, infertility, and an increased risk for ectopic pregnancy.[1-6] Because of the high prevalence of *C. trachomatis* among teenage girls, often without symptoms,[2] tracing infected persons and performing epidemiologic studies are difficult unless large-scale screening procedures are used.

Brunham et al.[7] have described a simple cotton swab test for the presumptive diagnosis of chlamydial infection. The purpose of this study was to determine whether the cotton swab test can be used in a population of young women who have few symptoms and whether examination of vaginal wet smear is of value in making a presumptive diagnosis of chlamydial infection.

Material and methods

The study population consisted of 148 consecutive teenage girls who were attending an outpatient youth clinic. The mean age was 17.4 years (range from 14 to 21 years). All but five had had sexual intercourse. Two were pregnant.

From the Department of Obstetrics and Gynecology, Gävle Central Hospital, Gävle Youth Clinic, and University of Uppsala, and the Department of Clinical Bacteriology, Gävle Central Hospital.
This investigation was supported by grants from Gävleborgs Läns Landsting.

The clinic is served by two midwives with special training and experience in birth control and teenage counseling. A consulting gynecologist visits the clinic 2 hours a week. The clinic has approximately 3000 patients annually. About 90% of patients come for birth control information and the remainder for treatment of a variety of gynecologic problems, such as suspected infection, bleeding, abdominal pains, and sexual problems. Eighty percent of all teenage girls living in the area attend the clinic before the age of 20. Hormonal contraception is used by about 70%. None of the patients in the study population had an intrauterine contraceptive device.

A history was taken, with special reference to vaginal discharge during the preceding 3 to 4 weeks, malodor, metrorrhagia, itching, and dysuria. When one or more of these complaints were present, the patient was classified as having a suspected infection. In the absence of these the patients were classified as having no infection suspected.

The patients underwent a gynecologic examination by the midwife for erythema of the vaginal wall, erythema and/or edema, and fragility of any cervical ectopy, mucupurulent discharge from the cervix or vagina, and malodorous discharge. When one or more of these signs were present, the patient was classified as having signs of infection; if none were present the patient was classified as having no signs of infection.

The ectocervix was wiped clean with a large cotton swab. A white cotton swab was inserted in the cervical canal by the midwife and a gynecologist classified the color of the swab as white, yellow, or blood-stained.

Table I. Relation between chlamydia culture and leukocyte count, clue cells, and bacteria in vaginal wet mount preparation

	Chlamydia culture				*Total (N = 148)*
	Positive		*Negative*		
	n	%	*n*	%	
Leukocyte count (No. per high-power field)					
0-3	5	11	41	89	46
>3 but fewer than No. of epithelial cells	6	10	54	90	60
More than No. of epithelial cells	7	19*	30	81	37
Wet smear missing	1		4		5
Clue cells					
Present	10	18	47	82	57
Not present	8	9†	78	91	86
Wet smear missing	1		4		5
Bacteria					
Cocci-dominated	12	16	62	84	74
Rod-dominated	6	9‡	63	91	69
Wet smear missing	1		4		5

*$\chi^2 = 1.125$ (NS); $0.20 < p < 0.30$ (more leukocytes than epithelial cells against fewer leukocytes than epithelial cells).
†$\chi^2 = 1.433$ (NS); $0.20 < p < 0.30$.
‡$\chi^2 = 1.215$ (NS); $0.20 < p < 0.30$.

Table II. Correlation between *C. trachomatis* culture and leukocyte count in vaginal wet smear and objective signs of infection

Chlamydia culture	*Wet smear (leukocyte count)*	*Vaginal inspection*		*Wet smear missing*
		No signs of infection	*Signs of infection*	
Positive	0-3	5	0	1 SI
	>3	3	5	
Negative	0-3	39	2	3 NI, 1 SI
	>3	73	11	
Total		125	18	5

SI, Signs of infection; NI, no signs of infection.

With a second swab discharge was collected from the posterior fornix, placed on a slide in a drop of saline solution, and evaluated by the gynecologist by microscopic examination. The gynecologist did not have any clinical information or previous knowledge of the patient.

The following parameters were noted in the wet preparation.

Leukocyte count. There were more white blood cells than epithelial cells in all five different high-power fields (×400). There were more than three white blood cells per high-power field (average of five) but fewer white blood cells than epithelial cells. There were up to three white blood cells per high-power field (average of five) in a preparation with vaginal epithelial cells thus indicating adequate sampling technique.

Bacteria. Bacterial flora was dominated by large rod forms (Döderlein flora). Bacterial flora was dominated by cocci or by short rods.

Clue cells (epithelial cells coated with bacteria). Clue cells were noted as being present or not present. Culture specimens for *C. trachomatis* were taken from the endocervix with ear, nose, and throat swabs. They were transported to the laboratory in 2SP medium and on arrival were either cultured or frozen at −70° C until cultured (always within 1 week). Cultures were grown in monolayers of cycloheximide-treated McCoy cells in 24-well racks.[8] All cultures were read after 48 hours with a fluorescein isothiocyanate–conjugated monoclonal antibody for staining (MicroTrak Culture Confirmation, Syva Corp., Palo Alto, Calif.).

Statistical analysis. The χ^2 test with Yates' continuity correction was used for statistical comparison.

Results

Nineteen of the 148 (13%) patients in the study had positive cultures for *C. trachomatis*. Infection was suspected from the history in 17 patients. Two (12%) of

Table III. Sensitivity, specificity, and positive and negative predictive value of parameters studied compared with *C. trachomatis* culture

	Sensitivity (%)	*Specificity (%)*	*Predictive value*	
			Positive (%)	*Negative (%)*
Signs of infection at clinical examination	32	89	30	90
Swab test (yellow)	26	66	11	86
Infection suspected by history	11	88	12	87
Wet smear				
More leukocytes than epithelial cells	39	76	19	90
Clue cells present	56	62	18	91
Dominance of cocci or short rods	67	50	16	91

these had positive cultures and 17 (13%) of the 131 patients with no history of infection had positive cultures. Accordingly, 90% (17/19) of the patients with *C. trachomatis* had no subjective symptoms of infection. The clinical evaluation classified 19 as having suspected infection. Six (32%) of these had positive cultures for *C. trachomatis* compared with 13 of the remaining 129 (10%). This difference is significant ($p < 0.025$). When the swab test specimen was evaluated as white, 12% (7/58) had positive cultures. When the swab test specimen was yellow or blood-stained 11% (5/47) and 18% (7/39), respectively, were positive (not significant). The correlation between chlamydia cultures and the wet smear evaluation is shown in Table I. None of the differences observed were statistically significant. When the wet smear showed up to three leukocytes per high-power field and no signs of infection were seen by inspection, five of 44 (11%) had positive cultures (Table II). Trichomonas was not seen in any of the wet mount preparations.

Comment

Chlamydial infection is a common finding in sexually active women and is generally more prevalent in women under 20 years of age. The cultivation of *C. trachomatis* is a slow, technically demanding, and expensive procedure. Several reports have focused on the possibilities of making a presumptive diagnosis of chlamydial infection. Brunham et al.[7] found a good correlation between endocervical mucopus with a yellow stain on a cotton swab and the presence of chlamydia in a population undergoing testing for sexually transmitted diseases. Harrison et al.[9] found a good correlation between the absence of *C. trachomatis* and a lack of fragility and erythema of the cervix in college students.

Our findings show that neither the cotton swab test nor the absence of fragility/erythema could be used to exclude chlamydial infections in a patient population similar to ours. Only 30% of the women who had positive cultures had signs of infection on examination and the subjective symptoms gave no further help. We conclude that neither the swab test, the vaginal wet smear, nor the history of the patient can give conclusive evidence of a chlamydial infection. Detection of chlamydia in this population can be done only by culture or other specific methods (Table III).

Evaluation of 1-deamino-[D-Tyr(Oethyl)^2,Thr^4,Orn^8] vasotocin, an oxytocin antagonist, in animal models of uterine contractility and preterm labor: A new tocolytic agent

D. W. Hahn, Ph.D., K. T. Demarest, Ph.D., E. Ericson, A.S., R. E. Homm, B.S., R. J. Capetola, Ph.D., and J. L. McGuire, Ph.D.

Raritan, New Jersey

We attempted to characterize the ability of a new oxytocin derivative, 1-deamino[D-Tyr(Oethyl)^2,Thr^4,Orn^8] vasotocin (ORF 22164), to antagonize the action of oxytocin in several in vitro and in vivo animal models of uterine hyperactivity. In these studies, the derivative was found to be a specific competitive inhibitor of oxytocin-induced contractions of pregnant guinea pig uterus in vitro. In addition, its intravenous administration induced a dose-dependent inhibition of oxytocin-induced uterine contractions in situ. Finally, like ritodrine, the drug induced a dose-dependent delay of ongoing labor in rats. These results suggest that 1-deamino-[D-Tyr(Oethyl)^2,Thr^4,Orn^8] vasotocin, unlike ritodrine, is a potent and specific antagonist of oxytocin-induced uterine contractions and thus may have potential clinical utility in the treatment of preterm labor. (AM J OBSTET GYNECOL 1987;157:977-82.)

Key words: Oxytocin, uterine hyperactivity, preterm labor

Much research has been conducted on preterm labor and labor-inhibiting drugs. However, the cause(s) of preterm labor is still not known, and the relative effectiveness and safety of various therapies are still unclear. Presently, the major treatment for preterm labor is the administration of selective β_2-adrenergic agonists that inhibit myometrial contractility by activation of receptor-mediated adenylcyclase. Unfortunately, treatment with β_2-adrenergic agonists has several liabilities, the primary one being the cardiovascular and metabolic side effects. In addition, although this therapy is very useful in the short-term treatment of preterm labor, its application in the long-term treatment of preterm labor is presently in question.[1, 2]

Oxytocin and vasopressin have been identified as possible causes of uterine hyperactivity in preterm labor.[3] A vasotocin derivative, 1-deamino-[D-Tyr(Oethyl)^2,Thr^4,Orn^8] vasotocin (deTVT; ORF 22164) has recently been reported to be a competitive antagonist of oxytocin[4] and may therefore be effective in inhibiting preterm labor. Our purpose was to examine the effect of the oxytocin antagonist deTVT in animal models for uterine contractility and preterm labor. Preliminary results of these studies have been published.[5]

Material and methods

Animals. Virgin female Hartley guinea pigs (Dutchland Farms, Pennsylvania) and female Wistar rats (Charles River Breeding Laboratories, Boston, Massachusetts) were housed in climate-controlled light/dark (12-hour cycle) rooms and given food and water ad libitum. In those studies with pregnant guinea pigs or rats, females were housed with males and the presence of vaginal plugs was designated as day 1 of pregnancy. In those studies with nonpregnant guinea pigs, the first day of vaginal opening was designated as day 1 of estrus.

Uterine contractility studies

In vitro. Mature guinea pigs on day 20 of pregnancy were used in these studies because the uterus at this time is in a progestin-dominant state. A 10 mm uterine segment was removed and suspended on a weighted (1 gm) lever system in an organ bath containing 35 ml of a physiologic solution (Van Dyke-Hastings) containing low calcium (0.6 mg/ml) maintained at 37° C and continuously gassed with O_2:CO_2 (95%:5%). All uterine strips were allowed to equilibrate 60 minutes before the onset of experimentation. Isotonic contractions were measured with a Phipps and Bird ST-2 linear motion transducer coupled to a Beckman recorder. The physiograph recordings of myometrial concentrations were quantified by integrating the area under the curves and are expressed as arbitrary planimetric units per 5 minutes.

In situ. Uterine contractility was estimated by mea-

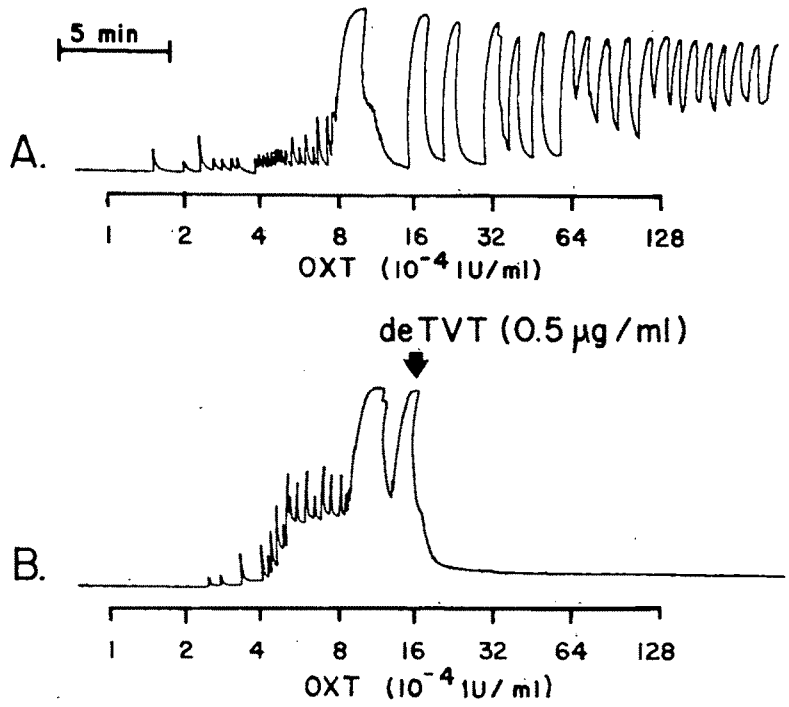

Fig. 1. The effect of deTVT on the oxytocin *(OXT)*-induced contractility of pregnant guinea pig uteri in vitro. Cumulative dose-response curves for oxytocin on myometrial strips were determined with **(B)** and without **(A)** the addition of deTVT (0.5 µg/ml).

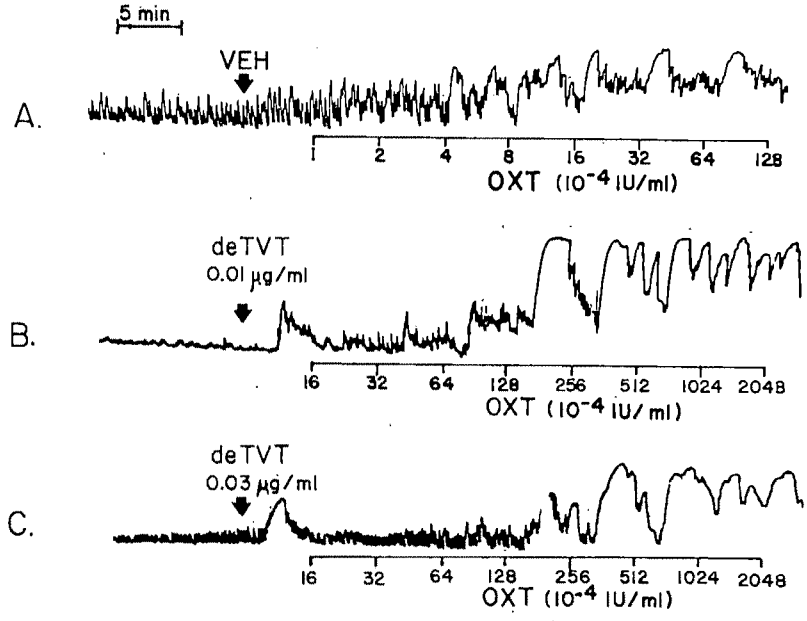

Fig. 2. Cumulative dose-response curve for oxytocin *(OXT)* on the contractility of guinea pig myometrial strips in vitro in the absence **(A)** or presence of deTVT, 0.01 **(B)** or 0.03 **(C)** µg/ml. *VEH*, Vehicle.

suring pressure changes in a cannulated perfused uterus in situ according to a previously published method.[6] Virgin female Hartley guinea pigs were anesthetized on day 1 of estrus with intraperitoneal pentobarbital sodium (35 mg/kg). Guinea pigs on day 1 of estrus (first day of vaginal opening) were used to ensure that the hormonal influences on the uteri were consistent. The external jugular vein was cannulated for drug

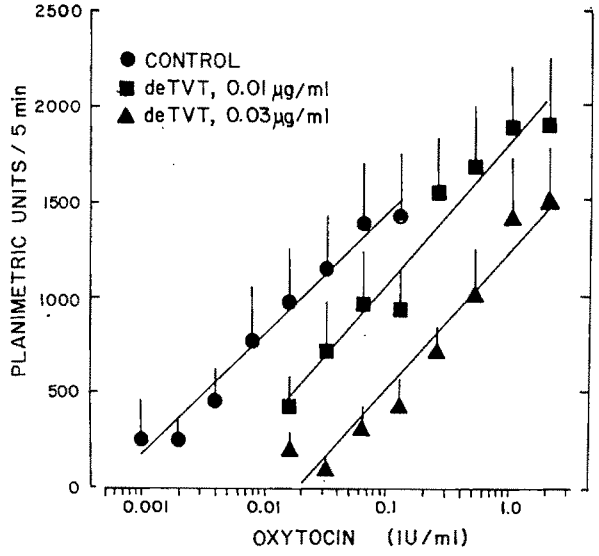

Fig. 3. Accumulated dose-response curves of oxytocin on the contractility of guinea pig myometrium in vitro with and without different concentrations of deTVT. Data are presented as the mean ± 1 SEM of five to seven determinations.

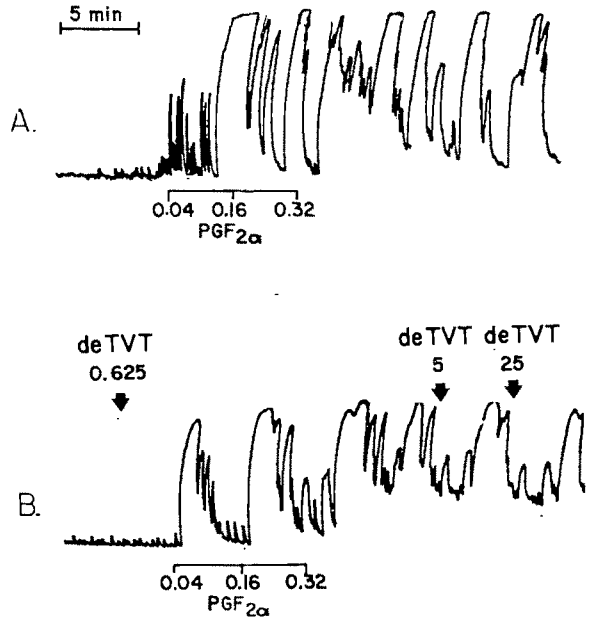

Fig. 4. The effect of deTVT on the prostaglandin *(PG)* $F_{2\alpha}$–induced contractility of pregnant guinea pig uteri in vitro. The effects of cumulative doses of prostaglandin $F_{2\alpha}$ (0.04, 0.16, and 0.32 μg/ml) were determined in the absence (**A**) and presence (**B**) of deTVT, 0.625, 5, and 25 μg/ml.

administration and the carotid artery was cannulated for the recording of arterial blood pressure. The uterus was cannulated at the uterotubal junction and a cannula was inserted through the cervix into the uterus and was ligated. The perfusate (distilled water at room temperature) was infused (0.5 ml/min) through the uterotubal junction cannula and was collected from the cervical cannula. Changes in uterine perfusion pressure were recorded with Beckman pressure transducers coupled to a Beckman Dynograph recorder. Responses in uterus tone were quantified in terms of millimeters of mercury pressure increases.

Preterm labor model, in vivo. The ability of drug treatments to delay the onset of labor was evaluated in a model that measures the spontaneous delivery time between the first and second rat pups in a term pregnancy.[7] Pregnant females were housed in individual plastic cages beginning on days 16 to 19 of pregnancy. On day 22 the females were observed continuously beginning at 8:30 AM. Immediately on delivery of the first pup, the female was administered the appropriate drug or vehicle treatment. The time of delivery of the first pup was recorded, and the female was returned to her cage and observed until delivery of the second pup. Data are expressed as time elapsed between the first and second deliveries.

Statistical analysis. Experimental data were initially analyzed with one-way analysis of variance. Between-group comparisons were made by the Student-Newman-Keuls test.[8] Differences with a probability of error <5% were considered significant.

Results

Uterine contractility studies

In vitro. An initial series of studies was undertaken to determine the effect of deTVT on oxytocin-induced contractions in isolated strips of pregnant guinea pig uterus. Oxytocin induced a dose-related increase in basal tone, amplitude, and frequency of individual contractions, with maximal effects obtained at 16×10^{-1} U/ml (Fig. 1). The administration of deTVT (0.5 μg/ml) completely abolished the oxytocin-induced contractions when dosed after maximal oxytocin-induced activity was reached. This antagonism was dose dependent and of a competitive nature (Figs. 2 and 3). When deTVT is administered before oxytocin, much higher concentrations of oxytocin are required to elicit the same degree of myometrial contractility. The cumulative results of these studies are summarized in Fig. 3. The dose-response curve for the effect of oxytocin on myometrial contractility is shifted to the right in a dose-dependent manner in the presence of increasing concentrations of the antagonist deTVT. This ability of deTVT to decrease the contractility of myometrial strips in vitro does not appear to be nonspecific action, because high doses of deTVT do not appear to affect prostaglandin $F_{2\alpha}$–induced uterine contractions (Fig. 4). These studies demonstrate that deTVT is a specific competitive antagonist of oxytocin-induced myometrial contractions in vitro.

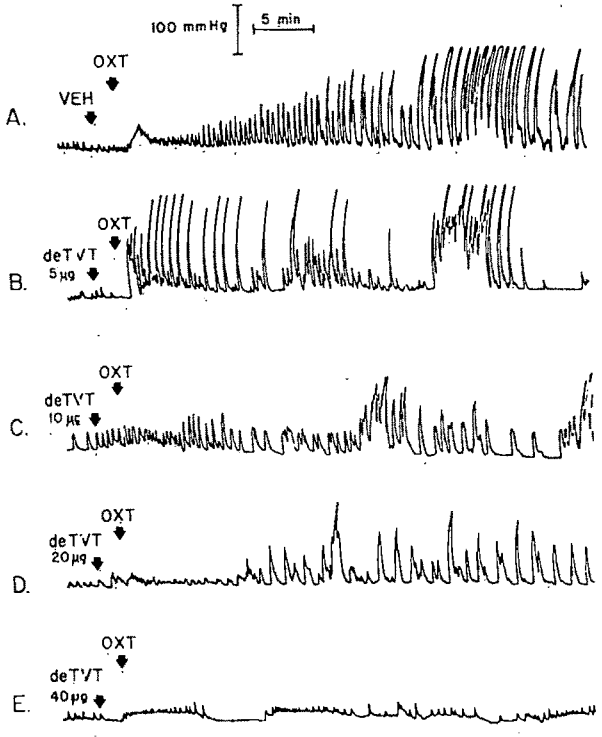

Fig. 5. The effect of deTVT on oxytocin *(OXT)*-induced uterine contractions in the guinea pig on day 1 of estrus in situ. All animals received an intravenous injection of oxytocin (0.4 IU) preceded by either an intravenous injection of deTVT or vehicle *(VEH)*. Uterine contractions were measured as changes in intrauterine pressure.

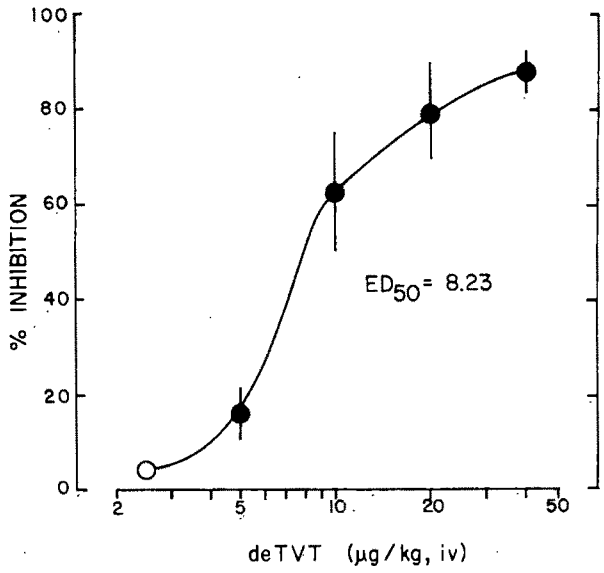

Fig. 6. Accumulated dose-response curves for the effect of deTVT on the inhibition of oxytocin-induced contractions in guinea pigs on day 1 of estrus in situ. Drug response was analyzed by integrating changes in intrauterine perfusion pressure over a 10-minute interval after dosing. Data are presented as the mean ± 1 SEM from five animals. The *solid circles* represent those values significantly different ($p < 0.05$) from control (0%).

In situ. The next series of experiments was undertaken to examine the ability of deTVT to block oxytocin-induced contractions in an in situ model of uterine hyperactivity. In these studies, oxytocin-induced changes in uterine contractility were quantified by measuring changes in uterine perfusion pressure in the presence or absence of deTVT in an anesthetized guinea pig on day 1 of estrus. Representative recordings from these studies are shown in Fig. 5. Intravenous oxytocin (0.4 IU/kg) induced a sustained increase in the frequency and amplitude of uterine contractions, as indicated by an increase in the intrauterine perfusion pressure. This oxytocin-induced increase was observed for at least 45 minutes. The administration of deTVT before oxytocin injection resulted in a dose-dependent decrease in both the frequency and amplitude of the oxytocin-induced contractions, with the highest dose (40 μg/kg) completely blocking the action of oxytocin. Fig. 6 clearly demonstrates that in situ deTVT antagonized the oxytocin-induced contractions of guinea pig uterus in a dose-dependent manner. The median effective dose for deTVT on the oxytocin-induced contractions of guinea pig uterus in this model was 8.23 μg/kg. These results demonstrate that deTVT is an effective antagonist of oxytocin-induced uterine contractions in situ.

Preterm labor model, in vivo. The final series of experiments was undertaken to compare the ability of deTVT and ritodrine, a β_2-antagonist, to antagonize spontaneous uterine contractions in an in vivo model of preterm labor.[7] In this model, pregnant rats were observed on day 22 of pregnancy (full term). Upon delivery of their first pup, either deTVT, ritodrine, or the respective vehicle was administered and the time until the delivery of the second pup was measured. Because deTVT is a peptide with a relatively short half-life, it (or its vehicle) was administered in doses of 100, 250, and 500 μg/kg subcutaneously every 5 minutes for 1 hour after the birth of the first pup; the maximal cumulative doses received were 1.2, 3.0, and 6.0 mg/kg, respectively. Both deTVT and ritodrine significantly delayed parturition compared with their respective vehicle-injected control groups (Fig. 7). Also, deTVT induced a dose-dependent delay in parturition, with the highest dose (500 μg/kg) being equivalent to the dose of ritodrine examined. These data demonstrate that deTVT, like ritodrine, is effective in vivo in delaying the progress of parturition after initiation.

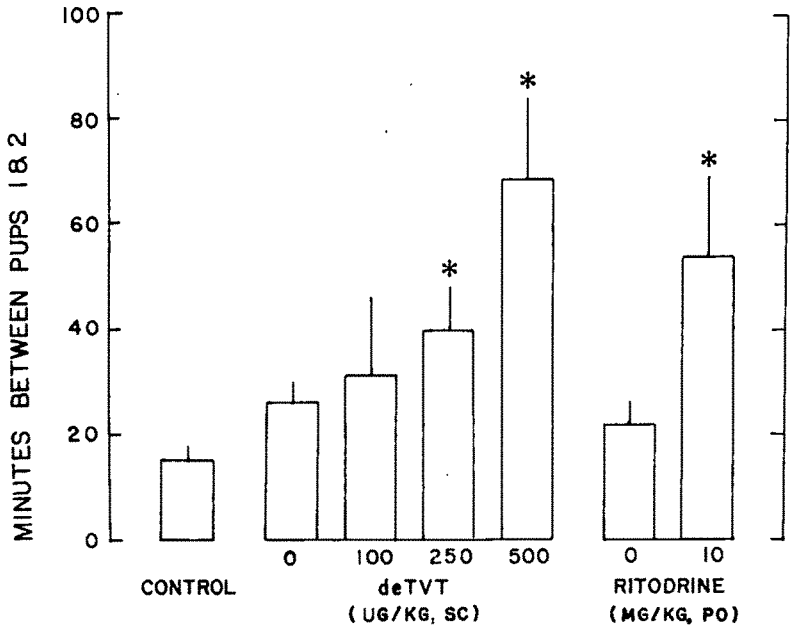

Fig. 7. Comparison of deTVT and ritodrine on the delay of parturition in rats. Each column represents the mean ± 1 SEM from five to six animals and is expressed as minutes elapsed between the deliveries of pup 1 and pup 2. *Significantly different ($p < 0.05$) from the respective vehicle-treated control.

Comment

Preterm birth is one of the major causes (75% to 80%) of perinatal morbidity and mortality. The social and economic consequences of preterm birth in terms of mental anguish and cost of caring for preterm infants and the associated lifelong infirmities are enormous. This is currently probably the most important problem to be addressed by modern obstetric research.[9]

At present, tocolytic treatment is not prophylactic, but commences after the onset of labor. The first line of treatment of preterm labor is the use of β-adrenergic agonists, but these agents are not the ideal therapy for preterm delivery. In fact, their use is associated with a high failure rate and a significant side effect liability.[9] The most common of these side effects is associated with β-agonist actions on the maternal cardiovascular system and metabolism.[10] Thus the development of specific new tocolytic agents without the side effect liability of the β-adrenergic agonists has an important clinical justification.

The present results demonstrate that deTVT is a competitive antagonist of oxytocin in vitro, as well as in vivo. In addition, these studies have demonstrated that deTVT is capable of delaying the progress of parturition after its onset in an in vivo model of preterm labor. These studies confirm previous results on the effect of deTVT on the oxytocin-induced contractions of rat and human uterine tissue in vitro.[4] Thus as an oxytocin antagonist, deTVT should be a highly specific agent with few side effects (since oxytocin receptors are found predominantly in uterus and mammary gland). Preliminary reports of clinical trials in which deTVT was effective in inhibiting uterine contractions during treatment of preterm labor support this contention.[11] In those clinical studies all patients reported a subjective relief of the undesired uterine activity and no side effects occurred. These pharmacologic properties make deTVT an ideal candidate for development as a new tocolytic agent.

Stereotypic behavioral response of rat fetuses to acute hypoxia is altered by maternal alcohol consumption

William P. Smotherman, Ph.D., and Scott R. Robinson, M.S.
Corvallis, Oregon

Transient compression of the umbilical cord has been implicated as a potential cause of unexplained brain damage and/or fetal death. We induced acute fetal hypoxia by compressing the umbilical cord of the fetal rat with a microvascular clamp. Direct observation of fetal behavior immediately after cord compression identified a three-phase behavioral response to acute hypoxia, consisting of an initial suppression in motor activity, a brief period of hyperactivity, and a secondary suppression of movement. All three phases occurred in <2 minutes from the onset of hypoxia. The stereotypic hypoxic response of rat fetuses may be adaptive as a means of removing mechanical sources of umbilical cord compression. Among fetuses exposed to alcohol in utero, the response to hypoxia was diminished in intensity and duration. Because of their altered hypoxic response, alcohol-exposed fetuses may therefore be at greater risk from transient cord compression in utero. (AM J OBSTET GYNECOL 1987;157:982-6.)

Key words: Fetal hypoxia, cord compression, fetal behavior, alcohol

Growth of the fetus and other changes that occur within the uterine environment increasingly confine the fetus during gestation and would seem to increase the chance of umbilical cord compression. Acute hypoxia resulting from compression of the umbilical cord in utero has been suggested as a significant source of brain damage and/or mortality among human fetuses.[1] There are a number of studies on the effects of hypoxia[2, 3] on fetal physiology. In most experiments, fetal hypoxia has been produced by manipulating oxygen availability to the mother, and fetal responses have been assessed by monitoring fetal heart rate or blood gases for an extended period. Little information exists on the immediate behavioral responses of fetuses to acute hypoxia, such as occurs after cord compression.

Our laboratory uses a technique that permits direct observation of rat fetuses during the last third of gestation. Briefly, pregnant rats receive a spinal anesthetic and are placed in a warm bath containing a physiologic solution. With the uterus externalized into this bath, fetuses may be delivered from the uterus, maintaining the placental-uterine attachment intact, and their behavior may be observed in detail.[4, 5] Thus the umbilical cord of rat fetuses can be compressed by application of a microvascular clamp, simulating a likely mechanism of umbilical occlusion in utero.

We report that acute hypoxia produced by clamping the cord is met by the rat fetus with a stereotypic behavioral response. The form and intensity of this response suggests that it may be adaptive in alleviating the source of cord compression. Rat fetuses exposed to alcohol in utero exhibit a diminished response to hypoxia, further suggesting that prenatal exposure to alcohol may place the fetus at greater risk from its own inadequate response to reverse transient hypoxia.

Material and methods

Adult female Sprague-Dawley rats (Charles River Laboratories, Wilmington, Massachusetts) were maintained under conditions of constant room temperature (22° C), regulated light cycle (12 hours light, 12 hours dark; lights on at 7 AM), and continuous access to food and water. Females were bred to Long-Evans males; this cross produces large litters of vigorous offspring ideally suited to prenatal study. Vaginal smears were taken over the period of breeding to identify the beginning of gestation (the first sperm-bearing smear was designated day 0). Animals were maintained and used in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals (Publication No. 85-23).

On day 20 of gestation, nine primiparous pregnant rats received a single oral intubation of a 20% w/v solution of ethanol in isotonic saline solution in a dosage of 4 gm ethanol per kilogram of female body weight. Ten nonintubated pregnant rats served as controls. (We have previously shown that unmanipulated fetuses are behaviorally equivalent to fetuses from mothers that receive a control intubation of isotonic saline solution.) Four hours elapsed between alcohol intubation and behavioral observation of fetuses. At this time the maternal blood alcohol content is 100 ± 20 gm/dl and a homogenate of fetal tissue shows an alcohol content of 78 ± 20 gm/dl.[6]

The methods used for preparation of the pregnant rat and subject fetuses are standard procedures in our laboratory and have been used extensively in studies of fetal behavior.[4, 5] With the rat under ether anesthesia, a chemomyelotomy was performed to chemically transect the rat's spinal cord between the first and second lumbar vertebrae, eliminating afferent stimuli from the lower body without the use of long-lasting general anesthesia. The duration of ether anesthesia was very brief (generally <60 seconds) and did not differ systematically between treatment groups. The prepared female was secured in a holding apparatus and her abdomen and hindlimbs were immersed in a bath of isotonic saline solution (Locke's solution) maintained at 37.5° C. The rat's uterus was externalized through a midline laparotomy and suspended just beneath the surface of the bath. A period of 15 to 20 minutes elapsed between the time of surgery and observation.

Two subject fetuses from each female were selected for behavioral observation. At the beginning of the observation period one subject fetus was delivered from the uterus and its amniotic sac into the bath, preserving the attachment of its placenta to the uterus. Immediately before the onset of observation, a microvascular clamp (RS-6470, Roboz Surgical Instrument Co., Washington, D.C.) was attached to the umbilical cord 5 to 10 mm from the fetus's abdomen. Attachment of the clamp applied 10 to 15 g of compression pressure, which was sufficient to effectively eliminate umbilical arterial and venous circulation during the observation period.

Beginning at the moment of attachment of the clamp, the fetus was observed for 2 minutes and each instance of its movement of the head, mouth, forelegs, rearlegs, or body trunk was recorded on a real-time event recorder. The sum of these individual movements provided a measure of total fetal activity. Because regional movements were defined independently, it was possible for them to occur at the same time. The incidence of such complex activity (the synchronous occurrence of two or more regional movements) was also examined. After observation of the first subject fetus, a second subject was delivered from the other uterine horn, the umbilical cord was clamped, and observation began. Only fetuses with good placental-uterine attachment were used as subjects. Comparison of observation records from different observers and reanalysis of videographic records have confirmed the high reliability of this observation protocol.[5, 7] Counts in the five regional categories and two derived categories (total and complex activity) were parsed into 5-second intervals over the 2-minute observation. Data from control and alcohol-exposed fetuses were compared in separate two factor repeated-measure analyses of variance. Experiments were carried out between 1 and 5 PM.

Results

Examination of the behavior of control fetuses from nonintubated mothers revealed a stereotypic response to transient hypoxia. Three distinct phases were identified in fetal behavior after occlusion of the umbilical cord (Fig. 1). In the first phase (approximately t_0-t_{30}), fetal movements decreased in frequency until they were almost completely suppressed. In a second phase (t_{30}-t_{75}) fetal activity rose sharply to a peak in excess of three times baseline rates of fetal movement. After the peak, a third phase was evident, as fetal movements again diminished in frequency until the end of the observation session (t_{120}). Fetuses exposed to alcohol exhibited less total activity than control fetuses ($F(1,36) = 13.1$, $p < 0.01$). Their activity peaked earlier and dissipated sooner than in controls, as indicated by the significant interaction between treatments and 5-second intervals ($F(23,828) = 2.0$, $p < 0.01$). Thus, although fetuses exposed to alcohol continued to show a response to hypoxia, it was diminished in magnitude and duration.

Examination of regional fetal movements indicated that only two categories—curl and head—differed when control and alcohol-exposed fetuses were compared (Fig. 1). In control fetuses, trunk curls occurred predominantly during phase II, coincident with the

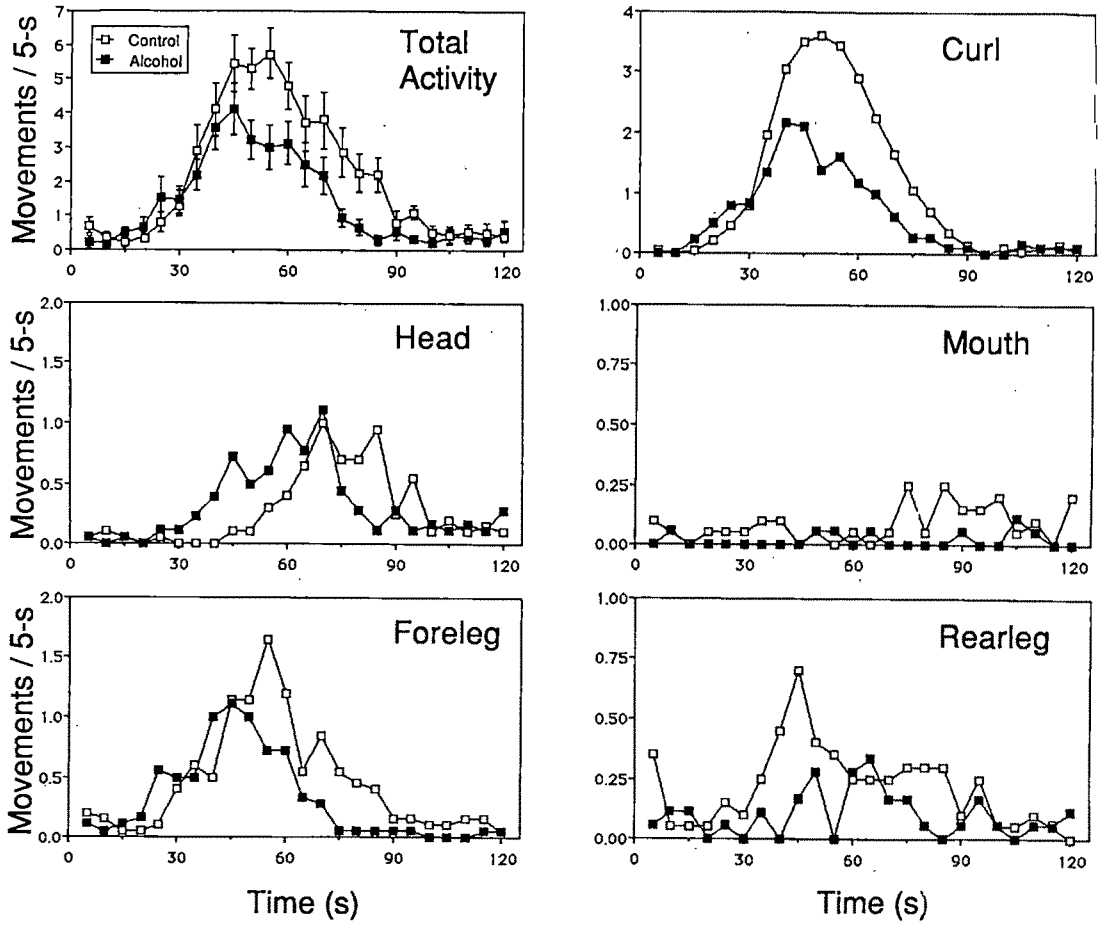

Fig. 1. Overall and regional activity of control and alcohol-exposed fetuses during 2-minute observations. The clamp was placed on the umbilical cord at t = 0. Points represent mean number of fetal movements per 5-second interval over the 2-minute observation. *Vertical lines* in the upper left figure depict the standard error of the mean. Unmanipulated 20-day-old rat fetuses move an average of 1.2 times every 5 seconds.[6]

sharp rise in overall activity. In fact, these vigorous lateral flexions of the body were the most common pattern of movement during the peak of activity. Head movements, in contrast, tended to occur during the secondary suppression of activity in phase III. Qualitatively, these head movements were also stereotypic, consisting of a rapid outward toss (cranial extension) of the head. Among alcohol-exposed fetuses these behavioral patterns continued to be associated with phases II and III, respectively. However, curls ($F(23,828) = 3.1$, $p < 0.01$) and head tosses ($F(23,828) = 2.2$, $p < 0.01$) occurred earlier in alcohol-exposed fetuses than in control fetuses. Three other categories of fetal movement (mouth, foreleg, rearleg) were uniformly suppressed after exposure to alcohol (all p values <0.01), but were not shifted in time relative to the onset of hypoxia.

In addition to simple movements, the incidence of complex activity (comprising two or more simultaneous movements) during hypoxic episodes was significantly suppressed by alcohol exposure ($F(1,36) = 8.2$, $p < 0.01$). Moreover, complex activity appeared to be much less common during hypoxia than among normal, well-oxygenated fetuses. We have previously described the emergence of complex activity during the last trimester of gestation in rat fetuses by comparing their occurrence with predictions from a model of random association of individual movements.[5] Briefly, if complex activities occur by accidental coincidence of simple movements, their frequency may be predicted as a relationship between the number of instances of fetal movement and the number of time intervals in which behavior is recorded. This relationship is expressed as:

$$f = B\left(\sum_{i=2}^{N} p^i\right)$$

where B is the number of intervals during an observation, N is the number of behavioral categories, p is

the probability of a fetal movement in an interval (estimated by the number of movements/B), and f is the predicted frequency of complex activity. This model of random association adequately accounts for the incidence of complex activity on days 16 and 17 of gestation, but by day 20 normal fetuses perform about 25% more complex activity than predicted.[5] We have interpreted these findings as evidence of increasing behavioral organization during the prenatal period. In contrast, under conditions of acute hypoxia, our control fetuses exhibited 68% fewer complex activities than predicted. This reduction in complex activity was not due to an overall suppression in activity; indeed, it occurred despite the exceedingly high rates of movement during phase II of the hypoxic response. Similarly, fetuses exposed to alcohol in utero performed 54% fewer complex activities than predicted during the period of hypoxia.

Comment

Clamping the umbilical cord appears to be a useful alternative to manipulating maternal oxygen availability to induce transient, acute hypoxia. Several minutes after the removal of the microvascular clamp at the end of the observation session, the rat fetus appears pink and well oxygenated, indicating that the clamp procedure has no lasting effect on umbilical circulation. Because the onset of umbilical clamping is well defined, it is possible to measure immediate and very brief responses to hypoxia that might otherwise go undetected. The reversible nature of umbilical clamping suggests that it may also be adaptable for use in the study of long-term consequences of transient hypoxia. As such, it may provide an animal model to explore the potential effects of transient compression of the umbilical cord during gestation.[1]

The period of time during which observations in this study were made, relative to the abrupt onset of hypoxia, is substantially shorter than has been used in previous studies of hypoxia.[2, 3] Indeed, the three phases of behavioral response to hypoxia are complete within 2 minutes of the placement of the umbilical clamp. The rapidity of the fetal response argues that transient episodes of hypoxia may be difficult to detect by traditional methods of examination and intermittent monitoring.

The brevity of the fetal hypoxic response does not, however, diminish its potential biologic significance. The striking reductions in synchronous activity suggest that hypoxia promotes a reorganization of fetal behavior. This interpretation is consistent with the view that the stereotypic lateral trunk curls and head tosses observed during acute hypoxia are specialized, reflexive movements that are not normally associated with the repertoire of spontaneous fetal behavior on day 20 of gestation. The stereotypy, intensity, and apparent reflexive nature of fetal behavior during acute hypoxia suggests that hyperactivity, and particularly lateral trunk curls and head tosses, are adaptive responses by the rat fetus to a sudden, deleterious change in its local environment.

If acute hypoxia may be induced in situ by pinching the umbilical cord against the wall of the uterus or the body of a sibling, as we believe likely, then vigorous outward-directed movements by the fetus may be useful in shifting body orientation or otherwise removing the source of the obstruction. Fetuses have been observed to change their body positions in utero and vigorous, whole-body movements have been implicated in effecting such changes.[8] The immediate motor response of fetuses to hypoxia is evidence of a kind of behavioral homeostasis ordinarily associated with adult animals: sudden detrimental changes in the intrauterine environment elicit behavioral responses from the organism that modify the uterine environment and restore favorable conditions.

Viewed in the context of adaptive behavior, the diminished activity of fetuses exposed to alcohol in utero assumes greater significance. Exposure to alcohol during gestation has been found to alter important features of the intrauterine environment, reducing amniotic fluid volume[6] and decreasing umbilical cord length.[9] A single exposure to alcohol is sufficient to cause transient constriction of the umbilical cord[10] and a marked suppression in fetal behavior. Fetuses exposed to alcohol are less active[6, 11] and less responsive to stimulation. The hypoxic response of rat fetuses exposed to alcohol is also diminished. Alcohol-exposed fetuses are less active overall and perform fewer lateral curls that subjectively appear less vigorous, and they perform these curls for a shorter period of time. They therefore appear to be less capable of responding adaptively to transient hypoxia and are less likely to have a mechanical impact on a source of umbilical cord compression. A single dose of alcohol administered to the mother is sufficient to suppress fetal activity for up to 4 hours.[6, 11] If the hypoxic response is impaired for a similarly extended period, then fetuses exposed to alcohol may be placed at significantly greater risk to transient hypoxia.

Effects of norepinephrine on lung fluid flow rate in the chronically catheterized fetal lamb

Motokazu Higuchi, M.D., Yuji Murata, M.D., Yoshiaki Miyake, M.D., John Hesser, M.D., James Tyner, Kirk A. Keegan, M.D., and Manuel Porto, M.D.
Irvine, California

The influence of norepinephrine on lung fluid flow rate was studied in seven chronically catheterized fetal lambs. Lung fluid was collected through a catheter inserted into the fetal trachea. In six experiments, continuous saline solution infusion for 1 hour followed by equivolumnar norepinephrine (3.0 μg/min) for 1 hour via the fetal jugular vein was carried out. In three additional experiments (two fetuses), a 3.0 mg intravenous bolus of propranolol was administered before norepinephrine infusion. Saline solution infusion did not influence the lung fluid flow rate or fetal biophysical and biochemical parameters. Norepinephrine increased fetal blood pressure by 22% and decreased lung fluid flow by 45% from control values. Lung fluid flow rate recovered within 2 hours after the end of the norepinephrine infusion. Pretreatment with propranolol did not alter the results. In addition to previous reports that demonstrated β-sympathomimetic agonist–enhanced reabsorption of lung fluid from fetal alveolar epithelial cells, our present results suggest that a reduction in fetal lung fluid secretion may be implemented as well through stimulation of α-sympathomimetic receptor sites in the pulmonary vasculature. (Am J Obstet Gynecol 1987;157:986-90.)

Key words: Fetal tracheal fluid, fetal lung fluid, fetal lamb, norepinephrine, propranolol

The fetal trachea, bronchi, and alveoli are filled with liquid during the prenatal period. This fluid was believed to be an aspirate of amniotic fluid until Olver et al.[1] confirmed that the major portion of fetal lung fluid was secreted from pulmonary capillaries into alveoli. Secretion of the fluid progressively increases as gestational age advances in fetal sheep,[2] and a large part of the lung fluid formed in the fetal lungs spills into the amniotic cavity.[3]

Recently, major interest has focused on the dynamics of fetal lung fluid production and the influence of catecholamines. Walters et al.[4] demonstrated that the secretion was inhibited at the level of epithelium by β-adrenergic receptor stimulation. There has been a common clinical observation of decreased amniotic fluid associated with the chronically distressed fetus or in the fetus with intrauterine growth retardation. In both conditions elevated catecholamine levels have been reported.[5]

The purpose of our study is to investigate the influence of exogenous norepinephrine on the fetal lung fluid dynamics in chronically instrumented fetal lambs.

Material and methods

Seven time-mated pregnant ewes (cross-bred Rambouillet-Columbia Suffolk, single gestation 127 to 132 days) were used. The pregnant ewe fasted 24 hours

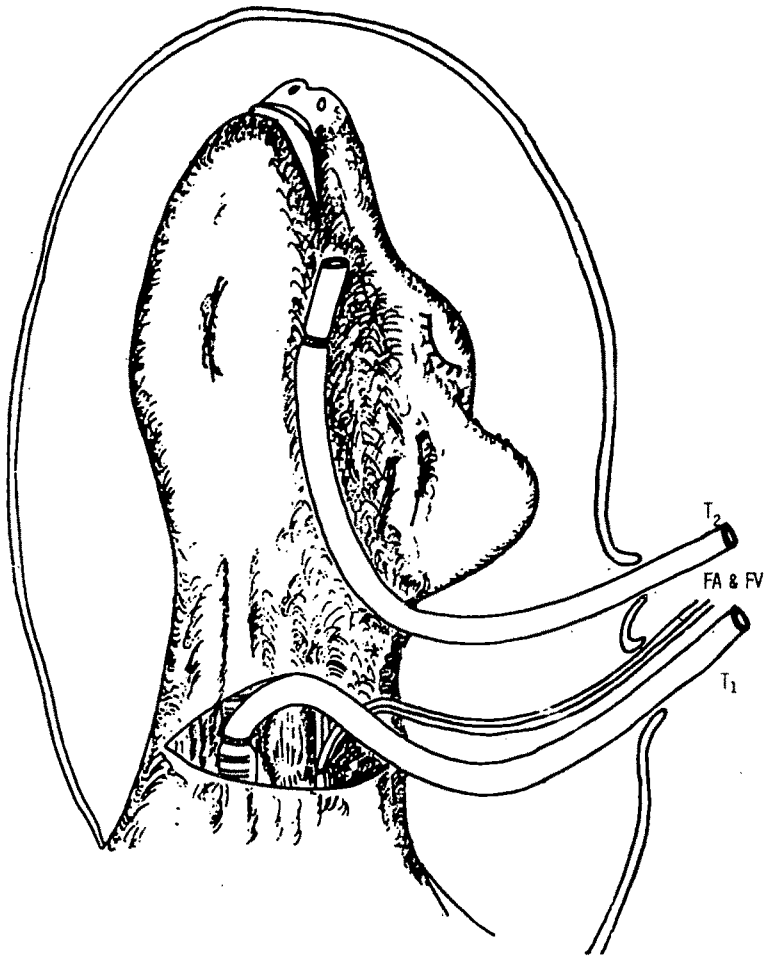

Fig. 1. A tracheal catheter (T_1) inserted in the fetal trachea and sutured securely for quantitative collection of fetal lung fluid. Another catheter (T_2) was connected to return lung fluid into the amniotic cavity while the experiments were not being performed. *FA*, Fetal artery catheter; *FV*, fetal vein catheter.

before surgery. The mother was anesthetized by intramuscular xylazine, 12 to 15 mg, and additional local anesthesia with 1% Xylocaine was given as needed during surgery. The uterus was exposed through a paramedian abdominal incision and the fetal head was delivered. Inspiration of air into the fetal lungs was prevented by covering the fetal head with a surgical glove filled with warm saline solution. Electrocardiogram electrodes were sutured under the fetal chest skin. The fetal carotid artery and jugular vein were catheterized. An open-end catheter was left inside the amniotic cavity to record urterine activity.

A catheter (4 mm inside diameter, 7 mm outside diameter, 100 cm in length) was inserted and sutured securely in the fetal trachea for quantitative collection of lung fluid (T_1, Fig. 1). A similar catheter was sutured on the fetal face with an open end located near the mouth (T_2, Fig. 1). The maternal femoral artery and vein were also catheterized. All catheters and elecrodes were exteriorized through the maternal flank.

The animals were allowed to recover in an air-conditioned stall where food and water were given ad libitum. During recovery, the two large catheters were connected to allow fluid produced in the fetal lungs to flow back into the amniotic cavity.

Experiments were performed on the fifth postoperative day or later. Before each experiment the catheter from the fetal trachea was connected with a sterile tubing to a sterilized polyvinyl collection bag. The tubing tip draining into the bag was adjusted in height to equal the resistance to fluid drainage into the amniotic cavity. Collection of fetal lung fluid was started 1 hour before the experiment to assure stable flow was achieved.

The protocol for the experiment consisted of the control period, saline solution infusion (0.1 ml/min), and norepinephrine infusion (3.0 μg/min = 0.1 ml/min), each of which lasted 1 hour. Postinfusion observation was maintained for 2 hours after the end of norepinephrine infusion (Fig. 2). Fetal arterial blood

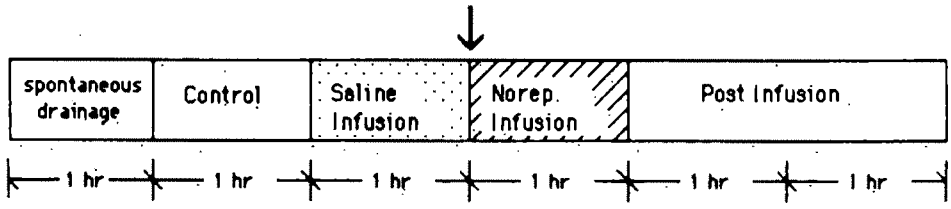

Fig. 2. Experimental protocol for quantitative collection of fetal lung fluid. Saline solution was infused at the rate of 0.1 ml/min; norepinephrine was infused at 3.0 μg/min in the same volume. Two fetuses (three experiments) received an intravenous bolus of propranolol, 3.0 mg, before norepinephrine infusion *(arrow)*.

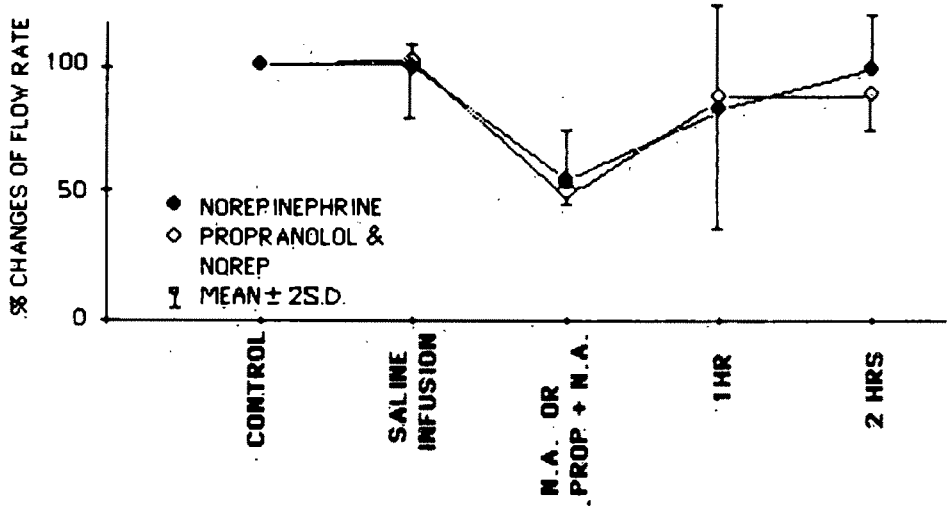

Fig. 3. Percent changes in fetal lung flow rate during saline solution infusion, norepinephrine with or without pretreatment with propranolol, and 1- and 2-hour recovery periods.

pH and gases and tracheal fluid flow rate were determined for each hourly collection period. Fetal heart rate and arterial pressure were continuously recorded on a multichannel recorder.

Six experiments were conducted in five fetuses following this protocol. An additional two animals (three experiments) received a bolus injection of propranolol (3.0 mg) before norepinephrine infusion. Electrolytes in the lung fluid obtained during the control and experimental periods were also analyzed.

Results

The mean (±SD) values of fetal arterial oxygen and carbon dioxide pressures and pH immediately before the experiments were 18.1 ± 1.6, 44.8 ± 1.4, and 7.37 ± 0.05 mm Hg, respectively. No appreciable changes occurred during the experiments. The average fetal heart rate was not consistently altered by norepinephrine infusion. The mean fetal arterial blood pressure exhibited an average increase of 22% from control.

Table I shows changes in the fetal lung fluid flow rate in five fetuses that received norepinephrine (six experiments) and two animals that received propranolol and norepinephrine (three experiments). The average lung fluid flow rate during the first observation period was 14.1 ml/hr (3.5 ml/kg/hr). Saline solution infusion did not significantly alter the flow rate. There was a significant decrease in the flow rate by 45.3% from control during norepinephrine infusion ($p < 0.001$, paired t test). The rate of fluid flow recovered within 2 hours after discontinuation of norepinephrine (Fig. 3).

Norepinephrine infusion after propranolol administration also decreased the fluid flow rate by 45.5% from control. This was not significantly different from the effect of norepinephrine alone ($p > 0.05$, Student's *t* test).

Table II shows electrolyte concentrations in the fetal lung fluid during control and norepinephrine infusion periods. No significant differences were observed.

Comment

The average hourly production of fetal lung fluid we observed during the control period was 3.5 ml/kg in the fetal lambs at approximately 130 days' gestation. This result agrees well with previous reports of 2.5 and 4.0 ml/kg by Normand et al.,[6] 4.5 ml/kg/hr by Mescher et al.,[7] and 300 to 400 ml/day cited by Enhorning et al.[8]

The mechanisms responsible for producing such a large amount of fluid in the fetal lungs are still not clear. Olver and Strang[1] have suggested a mechanism by which water is moved from the interstitium into the potential air spaces by active transport of chloride ion in the pulmonary epithelium against the gradient of protein osmotic pressure between lung alveoli and interstitial fluid or fetal plasma. Enhorning et al.[8] reported that the lung weight of fetal rabbits was reduced by treatment with isoxsuprine, and that the phenomenon was due to a decrease in the pulmonary fluid. Long-term administration of terbutaline, a selective β_2-receptor stimulant, to pregnant rabbits has also been shown to decrease the fetal lung-body weight ratio and to enhance secretion of surface-active material into amniotic fluid.[9] A marked decrease in tracheal fluid flow and increase in pulmonary surfactant efflux after the infusion of epinephrine to fetal sheep were also reported.[10] Furthermore, Brown et al.[11] observed that this epinephrine effect in reducing the lung liquid secretion became more remarkable with advancing gestation of the fetus. Walters and Olver[4] demonstrated that isoproterenol and epinephrine inhibited secretion of fetal lung fluid, and that the inhibitory effect was blocked with propranolol. The authors concluded that there was direct β-adrenergic stimulation of a liquid secretion mechanism at the pulmonary epithelial level.

Table II. Electrolytes in fetal tracheal fluid (mEq/L)

	Sodium	*Potassium*	*Chloride*
Control	138 ± 2.0	5.9 ± 0.4	201 ± 8.0
Norepinephrine	137 ± 1.0	4.8 ± 0.3	200 ± 7.0

Data are mean ± SD.

In our study, norepinephrine infusion significantly decreased the lung fluid flow rate, and the response was not modified by pretreatment with propranolol. The mechanism of flow rate reduction, therefore, is presumed to differ from the β-adrenergic stimulation at the pulmonary epithelium.

An increase in fetal pulmonary vascular resistance as a possible mechanism is supported by the observations made by Assali et al.[12] and Cassin et al.,[13] who separately reported a rise in pulmonary arterial pressure during norepinephrine injection in fetal sheep. It is therefore speculated that norepinephrine infused in the fetal lamb reduces the lung fluid net flow through its α-adrenergic effects on the pulmonary vascular beds.

Bland et al.[14] suggested and Kitterman et al.[15] demonstrated that a reduction of lung fluid in the fetal lamb under physiologic conditions may begin before birth. Brown et al.[11] attributed this to an increased plasma concentration of epinephrine during early labor. Reduced lung fluid in infants delivered vaginally is a common clinical observation. Human infants delivered vaginally without complication have been shown to have elevated catecholamine levels in cord blood,[16] and even moderate hypoxia has been reported to increase catecholamine levels markedly in fetal sheep.[17] A decrease in lung fluid secretion associated with parturition

and/or fetal hypoxia may be a preparatory process to clear the potential air space for the neonatal period.

Characteristics of the electromyogram recorded from the mesometrium of the pregnant ewe from 106 days' gestation to delivery: Similarities with and differences from the electromyogram obtained from the myometrium

J. P. Figueroa, M.D., A. Massmann, M.D., G. Pimentel, D.V.M., and P. W. Nathanielsz, M.D., Ph.D.

Ithaca, New York

Electromyographic recordings from 12 pregnant sheep were analyzed in four gestational age groups (106 to 115, 116 to 125, 126 to 135, and 136 to 145 days) and by the day of delivery. Mesometrial electromyographic activity was present in all animals studied. Contracture activity was synchronous in both mesometrium and myometrium. The frequency distribution of electromyographic events of different duration in the mesometrium was qualitatively identical to that recorded from the myometrium. The frequency of events <180 seconds was greater in the myometrium, while no difference was observed in contracture frequency. Mean contracture duration in myometrium and mesometrium shortened as gestation progressed ($p < 0.01$), and was of significantly shorter duration on the day of delivery when compared with all gestational age intervals ($p < 0.05$). Except at 135 to 145 days gestation and at the day of delivery, myometrial contractures were of significantly longer duration than mesometrial contractures. The presence of the endometrium and fetal membranes in the pregnant ewe may stimulate the myometrium, and account for the difference observed. In vivo recording of mesometrial electromyographic activity may provide an opportunity to study the paracrine regulation of myometrial activity. (Am J Obstet Gynecol 1987;157:991-8.)

Key words: Electromyography, mesometrium, endometrium

Myometrial electromyographic activity has been recorded in several species, in both nonpregnant[1-5] and pregnant[6-10] animals. Much of this work has been conducted in the sheep, because it is possible to relate myometrial electromyographic activity to a broad data base of physiologic information. Reports describing electromyographic activity based on visual analysis of frequency and duration of electromyographic events, while of value, lack precision on event quantification and definition of events with differing durations. Recordings of intrauterine pressure have also been used to characterize myometrial activity.[6,8] Visual evaluation of intrauterine pressure traces from short-term recordings, in terms of frequency and/or duration, may lose information. It is also difficult to use simple visual analysis to obtain information on patterns of activity over longer periods in pregnancy. In addition, intrauterine pressure changes during contractures are small and difficult to distinguish from movement and other potential artifacts.[11] The information obtained from myometrial electromyographic recordings is different from that obtained with intrauterine pressure recordings. Electromyographic recording represents the activity of all the various input factors that lead to the depolarization of the myometrial cells. It hence reflects a set of physiologic features different from those of the intrauterine pressure, which also involves changes in stimulus-contraction coupling.

With the use of continuous recording and computerized analysis, we have reported the myometrial electromyographic characteristics in the pregnant sheep after surgery.[9] Our data acquisition system and computer software allow us to determine the frequency distribution of electromyographic events of different duration. We have recently reported the electromyographic activity of the mesometrium in the nonpregnant ovariectomized sheep.[5] Mesometrial muscle fibers form a single, unidirectional layer of muscle continuous with the external layer of the myometrium. pregnant ewe, mesometrial electromyographic activity showed both similarities with and differences to myometrial activity. Contracture frequency was significantly greater in the mesometrium than in the myometrium both before and after estradiol administration to the nonpregnant ovariectomized ewe. Estradiol increased the short-term electromyographic events (<180 seconds) in the myometrium but not in the mesometrium. These differences may be attributed to paracrine regulation by the endometrium that underlies the myometrium but not the mesometrium.

Our aims were to record the electromyographic changes from electrodes placed on myometrium and mesometrium during the last third of gestation, to characterize the frequency distribution of electromyographic events of different duration, to compare mesometrial electromyographic activity with that recorded from the uterine horns, and to determine how the recordings at these two sites change throughout the last third of gestation and on the day of delivery.

Material and methods

Experimental animals. Twelve pregnant ewes of known gestational age were instrumented. Surgery was performed under halothane general anesthesia. Pairs of electromyographic electrodes were placed in myometrial and mesometrial tissue as previously described.[5, 6] In four of the ewes no further instrumentation was performed. Maternal and fetal vascular catheters were placed in the other eight ewes. The day of surgery was considered day 0. No analysis was performed until day 5 after surgery.

Recording of uterine electromyogram and data analysis. Uterine electromyographic activity was recorded and stored in a custom-built data acquisition system.[9] Event quantification was performed with a 2-hour running mean to set the threshold for distinguishing signal from noise. A 16-second period of activity below the threshold (the delimiter) was selected to determine when an event was completed. Recording of electromyographic activity was continuous and was analyzed in 24- and/or 1-hour blocks during the study. For frequency distribution analysis, electromyographic epochs were divided into 1-minute groups of burst duration lasting less than 1, 2, 3, 4, 5, 6, 7, 8, or 9 minutes. For further analysis, events were divided into two categories, <180 seconds (noncontracture activity) or >180 seconds (contracture activity). Mean contracture duration was calculated for each analysis block in each animal. The time for the noncontracture and contrac-

ture activities during which electrical activity was above threshold (total time active) during the analysis period was computed in each analysis block.

For convenience of analysis and to observe any gestational age–related trends, the study period was divided into five groups: four based on gestational age and also a group studied on the day of delivery. Data were available from four sheep from 106 to 115 days' gestational age (group A), six from 116 to 125 days' gestational age (group B), seven from 126 to 136 days' gestational age (group C), eight from 136 to 145 days' gestational age (group D), and seven on the day of delivery (delivery group).

Statistical analysis

Data were analyzed on the basis of the number of events per unit time, mean contracture duration (seconds), and total time active per 1-hour interval. Analysis on a 1-hour time base was considered necessary to avoid missing any rapid changes that may occur at the time of delivery. Data were available for at least 2 days in each animal included in any 10-day window (Table I). The total number of hours recorded from each animal are shown in Table I. Except on the day of delivery, only units of 24 hours of recording were analyzed, to avoid problems arising from circadian rhythms.[12]

The data from individual 24-hour intervals for each sheep were averaged to give one data point for each gestational age interval. The overall mean (±SD) was calculated from these data points. Means were compared between groups with the two-sample independent Student's t test. The Bonferroni correction was applied when multiple comparisons were performed. One-way analysis of variance was used for multiple mean comparisons. Statistical significance was set at the 0.05 level. Data throughout are presented as the mean ± SD.

Results

Characteristics of mesometrial electromyographic recordings. Mesometrial electromyographic activity was present in all animals studied. Fig. 1 shows the recording of mesometrial and myometrial electromyographic events and intrauterine pressure obtained from a pregnant sheep at 130 days' gestational age. Contracture-type activity was synchronous in all electromyographic leads as well as with the intrauterine pressure trace.

The frequency distribution for the number of electromyographic events of different duration in both myometrium and mesometrium at the four different gestational age intervals is shown in Fig. 2, *A* and *B*, and Fig. 2, *C* and *D*. The profile for the mesometrium is similar to that we have described for the myometrium in the pregnant sheep during the first 8 days after surgery, in that there are two populations of electromyographic events.[9] Noncontracture activity follows an exponential function and contracture activity follows a gaussian function. At all gestational age intervals (except 106 to 115 days), the number of shorter events (those <1 minute and those >1 but <2 minutes) in the myometrium was always greater than in the mesometrium ($p < 0.05$; Table II). In view of the clear separation of electromyographic events into two distinct groups, further analysis and comparison was based solely on two categories, noncontracture and contracture activity.

Characteristics and comparison of the two types of myometrial and mesometrial electromyographic events during the last third of gestation

Frequency of electromyographic events. Fig. 3 compares the frequency of noncontracture activity and contracture activity for the different intervals. Myometrial and mesometrial noncontracture and contracture frequency did not change significantly throughout the period of analysis. The frequency of events <180 seconds was greater in the myometrium than in the mesometrium. This difference was statistically significant at 116 to 125 and at 136 to 145 days' gestational age. Contracture frequency was not different at the two recording sites at any gestational age.

Mean contracture duration and total time active. Fig. 4 shows the mean contracture duration in both myometrium and mesometrium at the four different gestational age periods and on the day of delivery. Mean contracture duration shortened in both myometrium and mesometrium as gestation progressed ($p < 0.01$). Mean contracture duration was statistically shorter the day of delivery in both myometrium and mesometrium when compared with all other gestational age intervals ($p < 0.05$). Contractures were of significantly longer duration in the myometrium than in the mesometrium

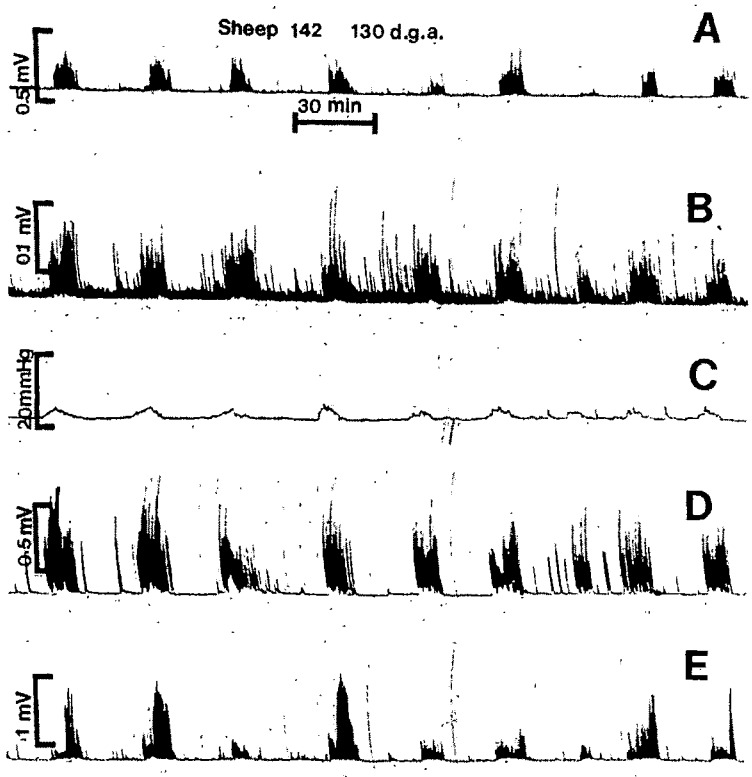

Fig. 1. Electromyogram recordings from a pregnant sheep at 130 days' gestation. **A,** Left mesometrium; **B,** myometrium of nonpregnant horn; **C,** amniotic pressure; **D,** myometrium of pregnant horn; **E,** right mesometrium.

at all gestational ages except 136 to 145 days and at delivery ($p < 0.05$).

Total time active (the sum of noncontracture and contracture activities) did not change during the last third of gestation in either myometrium or mesometrium. Although total time active was greater in the myometrium than the mesometrium at all intervals, it was statistically different only at 126 to 135 days' gestational age. In the mesometrium the total time active increased significantly on the day of delivery ($p < 0.05$) when compared with all other gestational age intervals (Fig. 5). Although total time active increased in the myometrium, this increase did not reach statistical significance.

Comment

Mesometrial electromyographic activity was present in all the pregnant ewes studied. Mesometrial activity was qualitatively identical to that recorded from the myometrium of the uterine horns. The frequency distribution of myometrial and mesometrial activity showed a profile identical to the one we have previously described for the myometrium of the pregnant sheep in the period immediately after surgery. Contracture electromyographic activity is generally, although not always, accompanied by an increase in intrauterine pressure. It is still not clear how to interpret noncontracture electromyographic activity. The noncontracture type of electrical activity is present throughout gestation, but only at delivery is it closely coupled with mechanical events. It is important to ask why the myocyte is able to depolarize and contract to produce the low-amplitude, long-lasting intrauterine pressure changes characteristic of contractures, but not the short, higher amplitude changes of contractions. It is possible that increased gap-junction density and/or permeability, such as occurs at the time of delivery, allows myocytes to contract synchronously, therefore developing more tension.[13-15] This possibility still does not explain the shorter duration of labor and delivery contractions. In addition, it is necessary to consider the effect of changes in the viscoelastic properties of the uterine connective tissue on the pattern of myometrial activity and the resultant effects of intrauterine pressure. We have previously shown that contracture-related electromyographic activity can be recorded simultaneously over most of the uterus.[16] Thus the low intrauterine pressure increment generated is not due

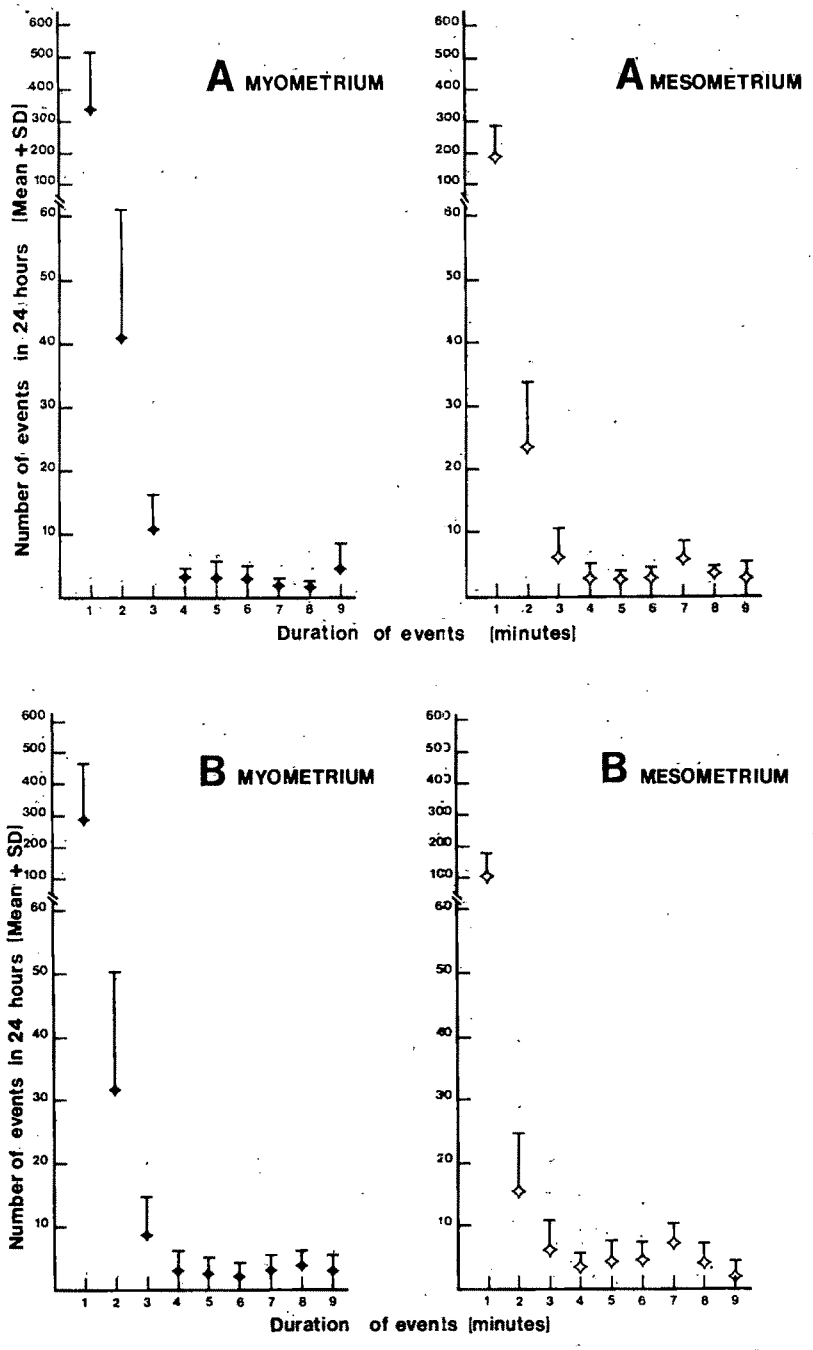

Fig. 2, *A* and *B*. Frequency distribution of electromyographic epochs of different durations in the myometrium and mesometrium in groups *A* and *B*. Epochs have been divided into 1-minute groups of burst duration.

to the fact that only a small portion of the myometrium is electrically active.

Preliminary data in the nonpregnant ovariectomized sheep show a late inhibition of electromyographic activity after exogenous oxytocin stimulation. It is possible to postulate an intrinsic mechanism within the muscle that will act to turn off contractile uterine activity. The extent of this inhibitory influence may depend on the intensity of the muscular contraction produced. The myometrium throughout gestation has more event activities <2 minute and the same contracture-type activity as the mesometrium. We hypothesize that the presence of endometrium in the nonpregnant ewe, and the fetal membranes in the pregnant

ewe, may stimulate the myometrium by means of short-lived modulators that cannot reach the mesometrium.

We thank Ms. Karen Moore for her help with the manuscript and Beth Elias for her assistance with the data analysis on the VAX 11/750.

β-Adrenergic receptor agonist infusion increases plasma prostaglandin F levels in pregnant sheep

Robert F. Casper, M.D., and Stephen J. Lye, Ph.D.
London, Ontario, Canada

Recent evidence of a stimulatory effect of β-adrenergic receptor agonists on prostaglandin production by human fetal membranes in vitro prompted us to investigate whether prostaglandins are increased during β-agonist infusion in vivo. On days 120 to 125 of gestation, blood samples were drawn from the aorta and vena cava of five crossbred ewes at 15-minute intervals for 1 hour before, during, and for 1 hour after a 3-hour infusion of isoproterenol (0.16 μg/kg/min) or normal saline solution. Plasma prostaglandin $F_{2\alpha}$ levels increased (177% ± 13% SEM over baseline; $p < 0.002$) in maternal aorta, while plasma 13,14-dihydro-15-keto prostaglandin $F_{2\alpha}$ levels increased in both aorta and vena cava (354% ± 47% and 309% ± 75% over baseline, respectively; $p < 0.002$) during isoproterenol infusion but not during saline solution infusion. No change was seen in plasma prostaglandin E_2 levels. The increase in plasma stimulatory prostaglandins in the pregnant ewe during β-agonist infusion is compatible with the increased uterine activity observed after myometrial desensitization by continuous β-agonist infusion. (Am J Obstet Gynecol 1987;157:998-1003.)

Key words: β-Adrenergic receptor agonists, prostaglandins, fetal membranes

Infusion of β-adrenergic receptor agonists is widely used in the treatment of preterm labor. Although these drugs are unquestionably effective in inhibiting uterine activity acutely, data to support a benefit in the reduction of the incidence of preterm birth are lacking. We have previously reported that human myometrium exposed in vitro to isoproterenol exhibited initial cessation of contractile activity, but contractions returned with continuous exposure to the β-agonist.[1] We have also demonstrated that this phenomenon, termed desensitization, occurs in vivo in the sheep with continuous infusion of ritodrine or isoproterenol.[2] The loss of sensitivity of the myometrium to the relaxing effects of β-adrenergic agonists was dependent on the mode of administration. When the short-acting β-agonist isoproterenol was administered in an intermittent fashion, inhibition of both sheep[2] and human[1] myometrial activity could be maintained.

In in vitro[1] and in vivo[2] studies, we observed that, with the occurrence of desensitization and return of myometrial activity, both the amplitude and frequency of contractions appeared to be greater than that seen before β-adrenergic agonist infusion. A possible mechanism for this observed increase in uterine activity is the production of a uterine stimulant due to administration of the β-agonist. Because recent studies have demonstrated that β-adrenergic agents are capable of stimulating prostaglandin (PG) production by human intrauterine tissues in vitro,[3-5] we investigated whether an increase in PG production might occur in vivo in pregnant sheep exposed to β-adrenergic agonist in-

fusion. If so, PGs may contribute to the increased uterine activity we observed after desensitization. We also measured plasma levels of PGE_2 and progesterone in these sheep, since infusion of a β-agonist into nonpregnant women during the luteal phase has been shown to decrease peripheral levels of these steroids,[6] which might in turn influence PG production. The demonstration of β-adrenergic stimulation of PG production would be an important effect to take into consideration when deciding on the use of these agents for the treatment of preterm labor.

Material and methods

Animals. With the animals under general anesthesia, surgery was performed on five pregnant, crossbred ewes between days 114 and 118 of gestation as previously described.[7] An amniotic cavity catheter was positioned for monitoring intrauterine pressure via a pressure transducer (Statham Instruments, Model P23, Oxnard, California) and stainless steel electrodes (Cooner Corporation, Chatsworth, California) were sutured into the myometrium of the pregnant uterine horn to record electromyographic activity. Intrauterine pressure and electromyographic activity were recorded on a Grass polygraph (Grass Instruments, Quincy, Massachusetts). Polyvinyl vascular catheters (VII Bolab, Lake Havasu City, Arizona) were inserted approximately 20 cm into the maternal femoral artery and vein, such that the tips of the catheters lay in the abdominal aorta and vena cava, respectively, 6 to 10 cm cranial to the branches of the uterine artery and the uteroovarian venous drainage. This catheter placement allowed sampling of peripheral blood (maternal aorta catheter) or blood enriched with uterine venous drainage (maternal vena cava catheter). The maternal external jugular vein was also catheterized with polyethylene tubing (PE100, Intramedic, Clay Adams, Parsippany, New Jersey) to permit peripheral infusions. The vascular lines were filled with sterile saline solution containing 4 U/ml sodium heparin and were flushed daily. The animals were given 7 days to recover from surgery and received food and water ad libitum.

Experimental protocol. On day 125 of gestation, between 8:00 and 10:00 AM, a 5 ml blood sample was drawn in a heparinized syringe from the maternal femoral artery and vein catheters every 15 minutes and stored immediately on ice. Within 15 minutes thereafter, cells were separated from plasma by centrifugation (4° C; 10,000 × g; 10 minutes). After 1 hour of baseline blood sampling, isoproterenol (0.16 μg/kg/min) or 0.9% sodium chloride was infused at a rate of 3 ml/hr for 3 hours. Blood sampling was continued for a further hour after the end of the infusion. The alternative infusion study was then done 48 to 72 hours later to give five isoproterenol studies and five saline solution studies. Plasma was stored at −20° C until assayed for prostaglandins, progesterone, or estradiol by radioimmunoassay.

Radioimmunoassay. The maternal artery and venous plasma concentrations of PGE_2, $PGF_{2\alpha}$, and 13,14-dihydro-15-keto $PGF_{2\alpha}$ (PGFM) were determined by specific radioimmunoassay as previously described.[8] Briefly, plasma was acidified (to pH 3) with hydrochloric acid and the PGs were extracted with diethyl ether (8 vol). The ether extract was evaporated to dryness under nitrogen and the samples were reconstituted with phosphate buffered saline solution. Incubations were then performed with specific antisera[8] and tritiated prostaglandins (Amersham, Oakville, Ontario, Canada). The inter- and intrassay coefficients of variation for each PG were <11% and <9%, respectively. Estrogen and progesterone were extracted from plasma with the use of diethyl ether and petroleum ether, respectively, and assayed by radioimmunoassay as previously described.[9] The interassay and intra-assay coefficients of variation were 10% and 8% for progesterone and 7% and 6% for estradiol, respectively.

Data analysis. Because of considerable between-

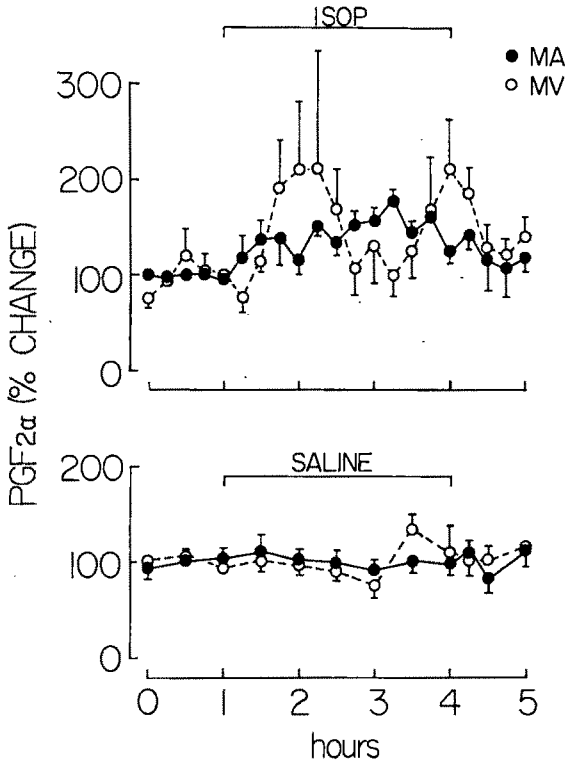

Fig. 1. Percent change from baseline in plasma $PGF_{2\alpha}$ levels in maternal vena cava (○) and maternal aorta (●) during isoproterenol *(Isop)* or saline solution infusions. A significant increase was seen in maternal aorta $PGF_{2\alpha}$ levels beginning at 105 minutes of infusion ($p < 0.002$). Maternal aorta $PGF_{2\alpha}$ levels returned to baseline by 15 minutes after isoproterenol infusion.

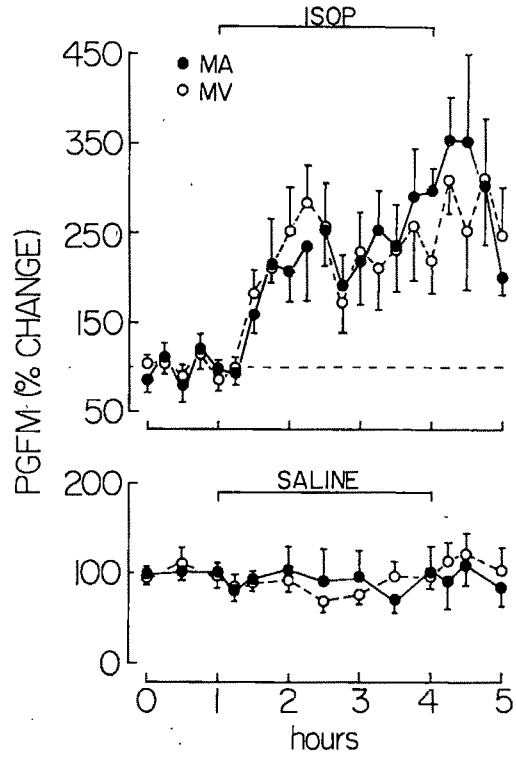

Fig. 2. Plasma PGFM levels shown as percent change from baseline during isoproterenol *(Isop)* and saline solution infusions. PGFM levels in maternal vena cava (○) and maternal aorta (●) increased significantly ($p < 0.002$) at 60 and 90 minutes, respectively. No significant change was seen during saline solution infusion.

animal variation in absolute PG levels, we have expressed the data as percentage change over pretreatment levels. Baseline concentrations of PGs were determined by calculating the mean of the five pretreatment samples; all samples were then expressed as a percentage of this mean. Data are shown as mean ± SEM throughout the article. To examine statistical significance between groups, data were subjected to analysis of variance and Duncan's multiple range test after determination of homogeneity of variance.

Results

Mean (±SEM) baseline levels of PGFM, $PGE_{2\alpha}$, PGE_2, progesterone, and estradiol were calculated from the first five plasma samples (Table I). Baseline values were higher in the uterine-enriched blood (maternal vena cava) than in peripheral blood (maternal aorta) for all hormones except PGFM, in which the values were equivalent.

$PGF_{2\alpha}$ levels increased in the maternal aorta during isoproterenol infusion, with the increase reaching significance ($p < 0.002$) after 105 minutes of infusion (Fig. 1). An apparent pulsatile pattern of vena cava $PGF_{2\alpha}$ levels was also observed, but did not result in a significant increase, likely because of variability in the frequency of $PGF_{2\alpha}$ pulses. No change in either aorta or vena cava $PGF_{2\alpha}$ levels was seen with infusion of 0.9% sodium chloride.

Plasma PGFM expressed as percent change from baseline is shown in Fig. 2 for isoproterenol- and saline solution–treated groups. During isoproterenol infusion, there was a progressive and significant ($p < 0.002$) increase in plasma PGFM levels in both maternal aorta and vena cava. This increase first reached significance after 1 hour of infusion in the vena cava and after 90 minutes in the aorta. The elevated levels continued after the end of the infusion, but appeared to begin to decline at 60 minutes after the infusion of isoproterenol. In contrast, no change was seen in PGFM levels during or after saline solution infusion.

PGE_2 levels did not change during isoproterenol infusion, except for a transient pulsatile release in the maternal vena cava immediately after the end of the infusion (Fig. 3). No change in aorta or vena cava PGE_2 levels was observed during or after saline solution infusion in the five sheep (data not shown).

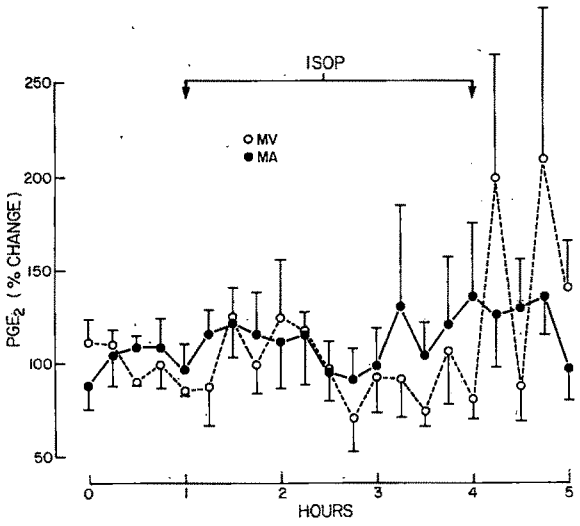

Fig. 3. Plasma PGE_2 levels expressed as percent change from baseline during isoproterenol *(Isop)* infusion. The levels in maternal vena cava (○) and maternal aorta (●) did not change significantly at any time during or after the infusion, although vena cava PGE_2 levels showed a marked pulsatile increase after the end of isoproterenol infusion.

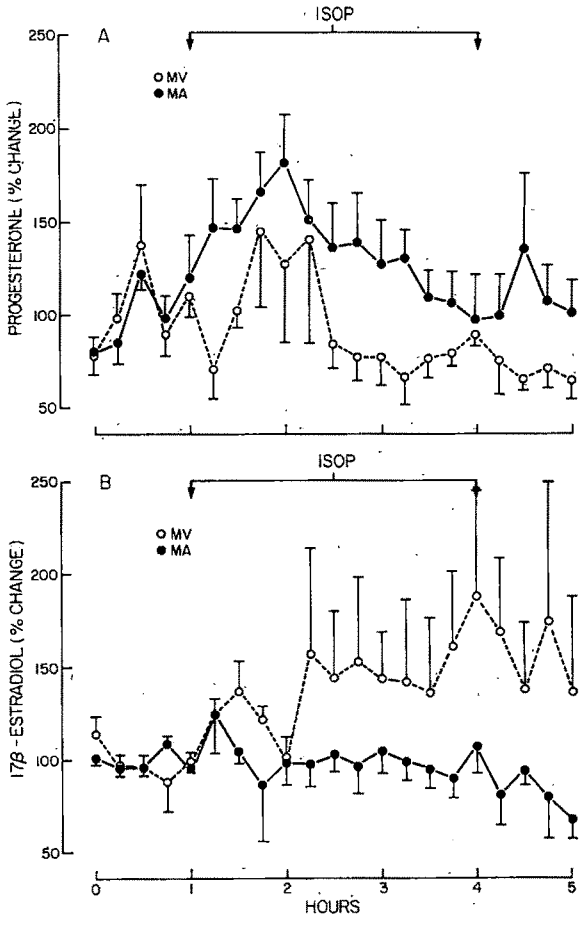

Fig. 4. Plasma progesterone **(A)** and 17-β-estradiol **(B)** levels in maternal vena cava (○) and maternal aorta (●) expressed as percent change from baseline. During isoproterenol infusion *(Isop)*, a significant ($p < 0.02$) but transient increase in plasma progesterone levels occurred initially in maternal aorta beginning at 45 minutes of infusion. No change was seen in the maternal vena cava progesterone levels or in 17-β-estradiol levels during isoproterenol infusion.

Plasma progesterone levels increased transiently ($p < 0.02$) after 45 minutes of isoproterenol infusion in the maternal aorta but not in the vena cava (Fig. 4, *A*). No change in progesterone levels was seen during saline solution infusion.

A variable response in vena cava plasma estradiol levels was seen in the five animals durring isoproterenol infusion (Fig. 4, *B*). In three animals, peak increases from 125% to 290% of baseline occurred, while two other animals demonstrated no change from baseline. No change was seen in maternal aorta estradiol levels during isoproterenol or saline solution infusions in any of the plasma samples.

These animals were not in labor at the time of any of the infusion studies, and quiescent uterine activity typical of a progesterone-dominant[10] environment was observed. Infrequent, low-amplitude increases in intrauterine pressure lasting 2 to 4 minutes and associated with an increase in electromyographic activity (contractures) occurred. There was no increase in uterine activity during either saline solution or isoproterenol infusion. However, a burst of electromyographic activity lasting approximately 5 minutes was often seen immediately after the end of isoproterenol infusion.

Comment

Our results demonstrate an increase in plasma levels of $PGF_{2\alpha}$ and its metabolite, PGFM, during infusion of the β-adrenergic agonist isproterenol in the pregnant ewe. The source of the elevated PG levels is likely the uterus or intrauterine tissues (that is, placenta or fetal membranes), because a significant gradient between the vena cava (uterine-enriched blood) and the aorta (peripheral blood) was observed for $PGF_{2\alpha}$. A similar gradient was not seen for PGFM, likely reflecting the major role of the lungs in the metabolism of $PGF_{2\alpha}$.[11, 12] Human fetal membranes and decidua have been shown to be a significant source of PG production. Skinner and Challis[13] demonstrated that dispersed cells of human amnion obtained at delivery produced more PGE_2 than $PGF_{2\alpha}$, while human decidual cells produced more $PGF_{2\alpha}$ than PGE_2. Chorionic cells appeared to play a mainly metabolic function, producing PGFM but not PGE_2 or $PGF_{2\alpha}$. Similar data have been reported by others.[4, 5]

To our knowledge, our study is the first to demonstrate increased plasma concentrations of stimulatory PGs in response to an in vivo infusion of a β-adrenergic

agonist during pregnancy. We chose isoproterenol for the experiments because of our previous data in sheep[2] demonstrating more rapid myometrial densensitization compared with ritodrine infusion. Our data contrast with in vivo reports in the rabbit[14] and baboon,[15] in which decreases in PGE and 6-keto-$PGF_{1\alpha}$ (the circulating metabolite of the inhibitory PG prostacyclin) levels, respectively, were found during infusion of the β-agonist ritodrine. These conflicting findings may reflect species differences or may be related to the type of β-agonist used. Ritodrine is a relatively selective β_2-receptor agonist, while isoproterenol has both β_1- and β_2-agonist activity. We are investigating the latter possibility. We found no rise in PGE_2 levels in our experiments, which differs from the in vitro results of β-adrenergic agonist (including isoproterenol) stimulation.[3-5] This finding may represent an interconversion of primary PGs in vivo. The presence of 9-keto PG reductase, which reduces PGE_2 to $PGF_{2\alpha}$, has been identified in ovine maternal and fetal blood.[16] The changes seen in estradiol and progesterone levels in our study are difficult to interpret. Estradiol levels increased inconsistently in the maternal vena cava during isoproterenol infusion, while those of progesterone increased transiently only in the maternal aorta. It is unlikely that these changes play a significant role in the alterations in PG levels that we observed. However, because fetal adrenal androgen may be a precursor of placental estradiol production,[17] it is possible that the rise in plasma estradiol levels in some sheep represents a fetal stress response to β-agonist infusion.

The pattern of PG elevations we report is similar to that occurring before and during adrenocorticotropic hormone–induced preterm labor in sheep. Olson et al.[18] demonstrated that $PGF_{2\alpha}$ and PGFM selectively increased in maternal vena caval and aortic plasma 16 hours or earlier before labor. No change was seen in PGE_2 levels. They concluded that the rise in stimulatory PGs occurred before the increased mechanical activity of the uterus during labor, suggesting that the rise in PGs was not a result of uterine activity. Rather, their findings implied that PGs promote the changes in contractility. Although no stimulatory effect of the PG elevation on myometrial activity was seen in the pregnant ewes we report, it is possible that long-term infusion may have lead to the onset of uterine contractions as observed by Olson et al. Alternatively, uterine activity in these sheep was suppressed by the high circulating levels of progesterone[10] normally present at day 120 of gestation. In preterm labor, in which uterine activity has already commenced, it is possible that myometrial sensitivity to PG action is enhanced and a stimulatory effect of the elevation of PGs may occur more rapidly.

At present, we cannot extrapolate our data to the human without measurement of PG levels in women during β-agonist infusion. However, if β-adrenergic agents also increase plasma PG levels in the human, our findings may be of interest clinically in view of the use of these drugs in the treatment of preterm labor. Recent observations, both in vitro[1, 19] and in vivo,[2, 20] have shown that continuous infusion of β-adrenergic agonists results in desensitization of the initial relaxing effect of these agents on the myometrium. Thus the current practice of continuous infusion of β-agonists for preterm labor, if prolonged to the point of desensitization, may lead to enhanced uterine sensitivity to the stimulatory effect of PGs on the myometrium. These factors may therefore contribute to the failure of β-agonist therapy in cases of clinical preterm labor.

Nifedipine: Effects on fetal and maternal hemodynamics in pregnant sheep

Bilal Harake, M.D., Raymond D. Gilbert, Ph.D., Stephen Ashwal, M.D., and Gordon G. Power, M.D.

Loma Linda, California

We investigated the effects of nifedipine, a calcium entry blocker, on the fetal and maternal circulation. Nifedipine was administered intravenously for 30 minutes to chronically instrumented pregnant ewes. Infusion of 5 $\mu g \cdot kg^{-1} \cdot min^{-1}$ resulted in a 30% to 50% increase in total and regional fetal cerebral blood flow to the brain stem, watershed, and subcortical regions ($p < 0.05$), without a significant change in fetal oxygenation or cardiac output. Infusion of 10 $\mu g \cdot kg^{-1} \cdot min^{-1}$ decreased uterine blood flow by 21% ($p < 0.001$) and fetal arterial oxygen content by 15% ($p < 0.01$), with no further increase in fetal cerebral blood flow. Maternal arterial pressure decreased and heart rate increased ($p < 0.001$) without variation of arterial blood gases. Significant plasma levels of nifedipine were detected in the fetal and maternal circulations. In view of the potential adverse effects on the fetus, further studies are needed before nifedipine is considered for use in human pregnancy. (AM J OBSTET GYNECOL 1987;157:1003-8.)

Key words: Nifedipine, calcium blocker, fetus, pregnancy, cerebral blood flow

Calcium entry blockers have been used effectively for the treatment of coronary artery disease, systemic hypertension, and supraventricular arrhythmias. Recent reports have also suggested potential therapeutic effects in several clinical conditions including premature labor,[1] dysmenorrhea, hypertrophic cardiomyopathy, preservation of the ischemic myocardium, peripheral vascular disease, cerebrovascular insufficiency, migraine headache, pulmonary hypertension, asthma, and esophageal spasm.[2]

Little information is currently available regarding the effects of these agents on the fetus or during pregnancy. Nifedipine, a dihydropyridine calcium entry blocker, has been shown to effectively control the hypertension accompanying preeclampsia and to exert a beneficial tocolytic effect in cases of premature labor without apparent adverse effects on either the mother or the newborn.[1, 3] However, recent animal studies have shown potentially hazardous effects reflected by a decrease in uterine blood flow and fetal oxygenation.[4, 5] Ducsay et al.[6] reported a marked tocolytic action of nifedipine accompanied by significant fetal acidosis and hypoxemia in pregnant rhesus monkeys. Our purposes were to investigate both maternal and fetal hemodynamic effects during maternal administration of nifedipine and to measure possible variations in fetal regional blood flow. We were particularly interested in

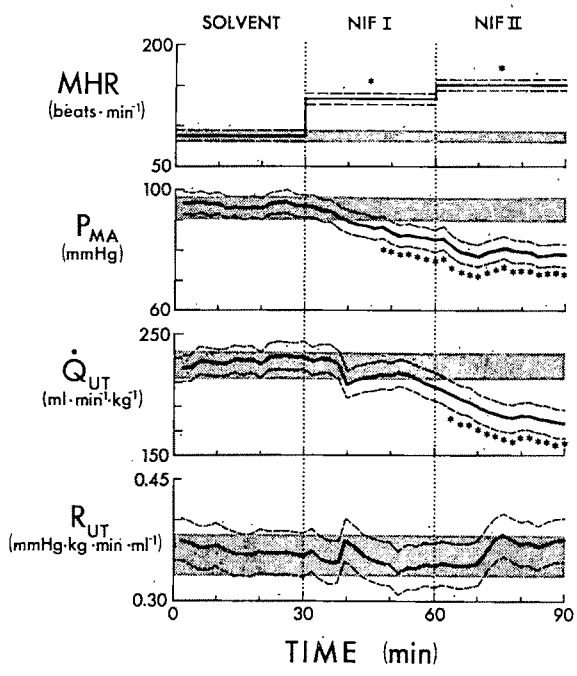

Fig. 1. Average maternal heart rate *(MHR)*, mean arterial pressure (P_{MA}), uterine blood flow ($\dot{Q}_{UT}$), and uterine vascular resistance (R_{UT}) during solvent and nifedipine infusions at 5 and 10 $\mu g \cdot kg^{-1} \cdot min^{-1}$. determining whether nifedipine was associated with changes in fetal oxygenation and the possible mechanisms of this response.

Material and methods

Animal preparation. We studied eight pregnant ewes of mixed-western breed with a gestational age of 123 to 138 days (term 147 days). All fetuses were singletons with a mean (±SD) weight of 3.2 ± 0.9 kg.

General anesthesia was induced with 20 ml of intravenous sodium thiamylal and was maintained, after intubation, by inhalation of 1.0% to 1.5% halothane and 30% nitrous oxide in oxygen. Surgery was performed as described by Lotgering et al.[7] in previous experiments in our laboratory. We placed catheters in the maternal descending aorta and inferior vena cava through a femoral artery and vein. Using a left flank retroperitoneal approach, we placed an 8 mm inside diameter electromagnetic flow probe (Zapeda Instruments, Seattle, Washington) around the common internal iliac artery. The uterus was subsequently exposed and, after a hysterotomy incision, catheters were introduced into the fetal ascending and descending aorta and inferior and superior vena cava. A catheter was placed in the amniotic cavity and two catheters were placed in the uterine vein. All incisions were closed and catheters led subcutaneously to a pouch on the ewe's flank. Postoperative care consisted of daily administration of 500 mg ampicillin injected into the amniotic cavity and 2 ml Combiotic (Pfizer Inc., New York, New York) administered intramuscularly to the ewe. Fetal arterial blood gases were measured daily to ascertain fetal well-being.

Experimental protocol. We allowed the animals to recover for 3 to 4 days after surgery. A 0.5 $mg \cdot ml^{-1}$ nifedipine solution was prepared the day of the experiment by dissolving 0.050 gm nifedipine (Pfizer Inc.) in 15 gm ethyl alcohol and 15 gm polyethylene glycol with water added to 100 ml solution. Because of its sensitivity to light, we handled nifedipine away from light sources and wrapped the infusion syringe with aluminium foil.

The experiment consisted of four consecutive phases, each lasting 30 minutes: control period, solvent infusion ($0.02 \text{ ml} \cdot kg^{-1} \cdot min^{-1}$), and nifedipine infusion at both 5 and 10 $\mu g \cdot kg^{-1} \cdot min^{-1}$. The infusions were administered through the maternal inferior vena cava by a Harvard Instruments pump. During the 2-hour experimental period, the following parameters were continuously recorded on a polygraph (Gould Inc. Model 2002, Cleveland, Ohio): maternal mean arterial pressure and heart rate, uterine venous pressure and uterine arterial flow rate, fetal heart rate and mean arterial pressure, and amniotic fluid and superior and inferior vena cava pressures. The fetal pressures were corrected for amniotic fluid pressure. Mean values were displayed every 10 seconds and stored on computer disk (Texas Instruments 990/10). During each phase of the experiment, blood samples were drawn every 10 minutes from the maternal descending aorta and uterine vein and from the fetal ascending aorta for pH, blood gas analysis (Radiometer Copenhagen, Denmark, type ABL 2d), and hemoglobin estimation (Radiometer America Inc., Cleveland, Ohio). Maternal and fetal blood samples were taken at 25 minutes of the last two phases for nifedipine plasma assays by gas chromatography (Harris Laboratories, Lincoln, Nebraska).

We measured fetal cardiac output and regional organ blood flow during each of the four phases of the experiment with radioactive microspheres 15 ± 1 μm in diameter labeled with scandium 46, chromium 51, ruthenium 103, and gadolinium 153 (New England Nuclear, Boston, Massachusetts). Microsphere infusions were peformed during the last 5 minutes of each phase. The ewe was killed at the end of the experiment by the administration of 20 ml of euthanasia solution (National Laboratories, Summerville, New Jersey). Fetal organs and placental cotyledons and membranes were weighed, ashed, and counted for radioactivity. The separated ashed organs were: kidneys, adrenal glands, heart, lungs, gastrointestinal tract, spleen, liver,

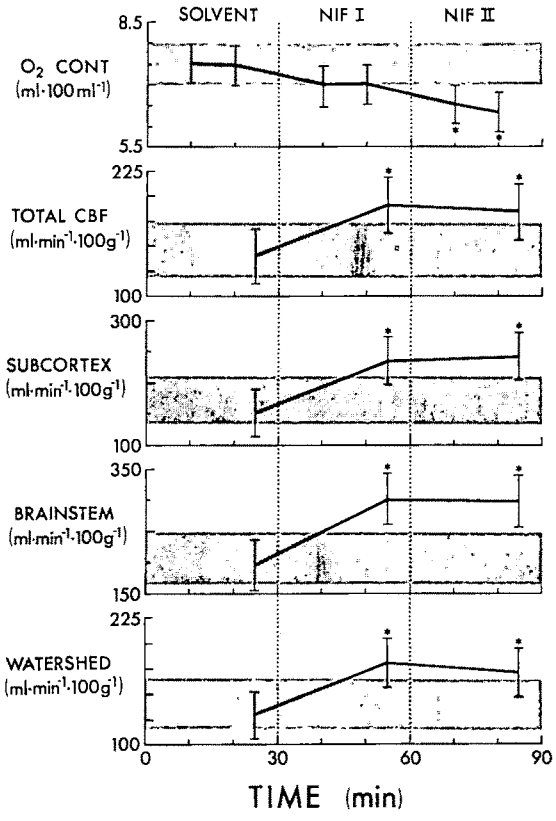

Fig. 2. Fetal ascending aorta O_2 content *(O_2 CONT)* and total and regional cerebral blood flow *(CBF)* during solvent and nifedipine infusions at 5 and 10 $\mu g \cdot kg^{-1} \cdot min^{-1}$. The horizontal *gray band* shows the 95% confidence interval of control values. All data are expressed within 95% confidence limit *(vertical bars)*. *$p < 0.05$ relative to control.

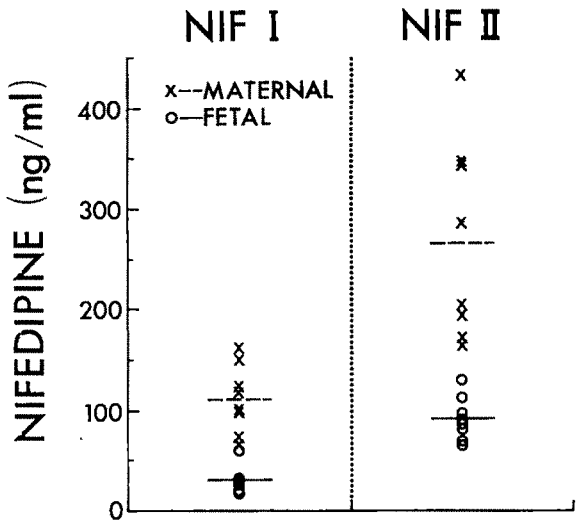

Fig. 3. Fetal and maternal plasma nifedipine levels at the end of 30-minute infusions of 5 *(NIF I)* and 10 *(NIF II)* μg/kg/min. *Horizontal lines* show mean values.

brain, total carcass, and placenta. The brain was dissected into five regions: brain stem, subcortex, gray matter, white matter, and watershed between the anterior-middle and middle-posterior cerebral arteries. Absolute fetal organ blood flow and cardiac output were computed from relative concentrations of radioactivity.[8] We calculated fetal arterial oxygen content, fetal cerebral vascular resistance, uterine oxygen consumption, and uterine vascular resistance during the different phases of the experiment. Vascular resistance was calculated as mean arterial pressure minus venous pressure divided by organ blood flow.

Statistical analysis. Unless otherwise stated, values are expressed as means ± SEM. We tested differences between means of control values and experimental measurements by two-way analysis of variance and Duncan's multiple-range test. A p value <0.05 was considered to indicate significance.

Results

Maternal and fetal hemodynamics. Maternal hemodynamic responses during solvent and nifedipine infusions are shown in Fig. 1. There were no significant changes in heart rate or mean arterial blood pressure during solvent infusion. Maternal heart rate increased and blood pressure decreased progressively during nifedipine infusion ($p < 0.001$). During the control period, the average uterine venous pressure, oxygen consumption and vascular resistance were 14.1 ± 1.6 mm Hg, 7.0 ± 0.8 ml · min^{-1} · kg^{-1}, and 0.35 ± 0.02 mm Hg · kg · min · ml^{-1}, respectively; none of these values showed significant variation with either solvent or nifedipine infusion. The uterine blood flow decreased by 21%, from a control value of 224 ± 7 to 177 ± 11 ml · min^{-1} · kg^{-1} at the end of the experiment ($p < 0.001$). The control fetal mean arterial pressure and heart rate were 47.7 ± 2.8 mm Hg and 170 ± 9 bpm, respectively, with no change observed during the experiment.

Maternal and fetal blood gases. Maternal blood gas values during the control period were: Pa_{O_2}, 96.2 ± 2.9 mm Hg; Pa_{CO_2}, 37.7 ± 1.2 mm Hg; and pH, 7.45 ± 0.01; these values did not change significantly during the study. Fetal Pa_{O_2} fell progressively during nifedipine infusion without reaching statistical significance (Table I). However, fetal arterial O_2 content (Fig. 2) and O_2 saturation (Table I) significantly decreased at the end of nifedipine infusion ($p < 0.01$ and $p < 0.001$, respectively).

Fetal organ blood flow. Fetal organ blood flows tended to increase with nifedipine, but only brain blood flow reached statistical significance. During the control period, blood flow to the brain, heart, and adrenal glands was 146 ± 16, 228 ± 26, and 377 ± 68 ml · min^{-1} · 100 gm^{-1}, respectively; the heart and ad-

renal glands manifested an increase, relative to control, with solvent as well as nifedipine. Control fetal cardiac output was 496 ± 56 ml · min⁻¹ · kg⁻¹; there was no significant variation during other phases of the experiment. Fig. 2 shows the variations in total and regional cerebral blood flow. Control blood flows to the brain stem, subcortical, and watershed regions were 204 ± 25, 171 ± 19, and 139 ± 19 ml · min⁻¹ · 100 gm⁻¹, respectively. The brain stem showed a 50% increase in flow during both nifedipine infusions, and a 30% to 42% increase in flow was observed in subcortical and watershed areas. Control blood flows to gray matter and white matter were 141 ± 16 and 108 ± 14 ml · min⁻¹ · 100 gm⁻¹, respectively; these values did not vary significantly after nifedipine infusion. No significant change in cerebral blood flow was observed with solvent infusion. During the control period, the average cerebral vascular resistance, calculated from five animals for which complete data were available, was 0.029 ± 0.004 mm Hg · kg · min · ml⁻¹; it decreased by 24% ($p < 0.05$) during the first nifedipine infusion. There was no significant change in this parameter during other phases of the study.

Nifedipine plasma levels. Fig. 3 shows individual and average plasma levels of nifedipine. At the end of the first infusion (5 μg · kg⁻¹ · min⁻¹), average fetal and maternal plasma levels were 29 ± 5 and 110 ± 12 ng · ml⁻¹, respectively; at the end of the second infusion (10 μg · kg⁻¹ · min⁻¹), fetal and maternal levels were 91 ± 8 and 267 ± 35 ng · ml⁻¹, respectively.

Comment

Our study has shown that nifedipine significantly altered maternal and fetal hemodynamics. Nifedipine infusion resulted in a progressive decrease in maternal mean arterial pressure and uterine blood flow. Because uterine vascular resistance did not vary significantly, the fall in uterine blood flow could be explained entirely by the hypotensive effect of nifedipine. In contrast to our findings, Veille et al.[9] did not observe any significant change in uterine blood flow in response to bolus injections of 20 to 40 μg · kg⁻¹ and described only a transient fall in maternal arterial blood pressure in the first minute after the boluses. Although our data differ from those of Veille et al., both studies indicate that the decreased uterine blood flow associated with nifedipine occurs only with a significant decrease in maternal arterial pressure. In other studies of calcium entry blockers, nicardipine[4] and verapamil[10] significantly decreased uterine blood flow in pregnant rabbits and ewes. Contrary to these findings, nifedipine has been shown to increase uterine blood flow in the nonpregnant rat,[11] which could be attributed to a decrease in uterine vascular resistance. These data suggest that the vasodilator effect of nifedipine on the uterus is not present during pregnancy. Whether these observations are related to the overall physiologic vasodilation that occurs in pregnancy or to the anatomy of placental vasculature is still to be determined. Our data do not differentiate between myoendometrial and placental flow. Parisi et al.[12] have shown that nicardipine administered during angiotensin II infusion caused vasodilation in the myoendometrium, but no change in placental resistance occurred. Whether such a difference in response might have occurred in our experiment is not known; however, it is probably unlikely because total uterine resistance did not change.

Nifedipine infusion resulted in a trend toward fetal hypoxemia and acidemia. These changes were significant at higher doses (10 μg · kg⁻¹ · min⁻¹) and agree with the findings of Ducsay et al.,[6] who reported a dramatic decrease in fetal arterial pH and partial O_2 pressure (from 21.7 to 14.2 mm Hg) during continuous nifedipine infusion at 3 μg · kg⁻¹ · min⁻¹ in pregnant rhesus monkeys. In all these reports, there was no variation in maternal arterial pH or blood gases. In our study, fetal hypoxemia was most probably related to the 21% fall in uterine blood flow. In the fetal lamb, Skillman et al.[13] observed a decline in arterial Po_2 and O_2 content with reductions of 24% to 63% in uterine blood flow. They concluded that the amount of fetal hypoxia was a direct consequence of the degree of restriction in uterine blood flow.

Our data and those of other investigators[6] did not

show any significant fetal hypotension with nifedipine. The mechanism of this difference from the adult response is uncertain; whether it is dose related or a result of opposing effects to nifedipine and hypoxemia on fetal resistance vessels needs to be determined.

Little information is currently available on the effects of calcium entry blockers on fetal organ blood flow. With the use of nicardipine, Holbrook et al.[4] reported increases in blood flow to the fetal brain and myocardium of 61% and 183%, respectively. In our experiment, only total and regional cerebral blood flows were increased by nifedipine. The increases in myocardial and adrenal blood flows were not significant because similar changes occurred during solvent infusion. The increase in total cerebral blood flow was associated with a significant drop in cerebral vascular resistance during the first infusion; the unsustained decrease in resistance during the high-dose infusion was probably due to individual variability and to the limited number of animals. Several calcium entry blockers, particularly nimodipine and nifedipine, have been shown to vasodilate cerebral vessels in vitro and to increase cerebral blood flow in vivo.[14, 15] In most of these studies, a 50% to 100% increase in both total and regional cerebral flow was observed during infusions of 1 to 10 $\mu g \cdot kg^{-1} \cdot min^{-1}$. These findings have been reported in a variety of species, in adult nonpregnant as well as newborn animal models.[16]

It is possible that during the 10 $\mu g \cdot min^{-1} \cdot kg^{-1}$ nifedipine infusion, fetal hypoxemia contributed to the increase in cerebral blood flow. Longo et al.[8] showed that hypoxemia in sheep increased blood flow to the fetal brain, heart, and adrenal glands. In our study, a nifedipine infusion of 10 $\mu g \cdot kg^{-1} \cdot min^{-1}$ decreased O_2 content 15% and was associated with a 29% increase in cerebral blood flow. However, the maximum increase in fetal cerebral blood flow occurred at the lower infusion rate (5 $\mu g \cdot kg^{-1} \cdot min^{-1}$) and was not accompanied by any appreciable change in oxygenation. Furthermore, nifedipine infusion at 10 $\mu g \cdot kg^{-1} \cdot min^{-1}$ did not result in any additional increase in cerebral blood flow, or blood flow to any other fetal organ, although the fetal arterial O_2 content was significantly decreased. Thus our data indicate that the maximal increase in fetal cerebral blood flow occurred at lower doses without any significant change in either uterine blood flow or fetal oxygenation, suggesting that nifedipine had a direct cerebral vasodilatory effect.

These dose-related effects might have potentially important clinical implications, because significant tocolytic effects appear at relatively low doses in the range of 4 $\mu g \cdot kg^{-1} \cdot min^{-1}$.[3] However, more studies are needed, perhaps with fetal infusions of nifedipine, to differentiate between direct fetal effects and changes secondary to alterations in maternal circulation. We emphasize that our findings apply mainly to conditions during normal pregnancy. In cases of hypertension accompanying pregnancy, a clinical trial of nifedipine[1] apparently did not result in any adverse effect. In contrast, the administration of nicardipine to 15 hypertensive ewes resulted in fetal hypoxia, acidosis, and the alarming death of five fetuses.[12]

It is difficult to interpret our findings of increased cerebral blood flow in relation to the well-being of the fetus. In the term fetus, cerebral germinal matrix vasculature is well developed and unlikely to bleed in response to increases in flow or perfusion pressure. In the preterm fetus, periventricular ischemia contributes to the development of hemorrhage, and reducing such ischemia should decrease the risk of its complications. However, in cases of hyperperfusion, serious concerns arise because of the association with intracranial bleeding.

Nifedipine crossed the placenta with significant levels detected in the fetal circulation. Fetal-to-maternal plasma concentration ratios were 0.3 and 0.4 during infusions, resulting in fetal plasma levels of 29 ± 4 and 91 ± 8 ng $\cdot$ ml^{-1}. Based on adult human studies, sublingual administration of 10 to 40 mg nifedipine to healthy volunteers resulted in plasma levels ranging between 28.7 ± 3.7 and 138.7 ± 43.7 $\mu g \cdot ml^{-1}$.[17] Ulmsten[1] used similar doses to treat normotensive and hypertensive patients with premature labor. We suggest that the plasma levels in our study corresponded to optimal nifedipine dosages in sheep.

In conclusion, during the intravenous administration of nifedipine to the pregnant ewe, uterine blood flow and fetal arterial oxygen content decreased while fetal cerebral blood flow increased. This increase in cerebral blood flow preceded any significant change in fetal oxygenation. Nifedipine crossed the placenta and significant levels were detected in the fetal circulation. In addition to its antihypertensive and tocolytic effects demonstrated in previous studies, we speculate that nifedipine may play a therapeutic role in cases of fetal distress and compromised cerebral circulation. However, because of the potential deleterious effects of nifedipine on the fetus, further studies are needed before this agent is considered for use in human pregnancy.

The technical assistance of Lela Spears, Dong Quan-Sheng, and Steven Dale is greatly appreciated. We thank Pfizer Inc. for providing nifedipine powder and Harris Laboratories for performing nifedipine plasma assays.

Absence of clomiphene and/or active metabolites in blood of clomiphene citrate–treated patients during organogenesis: Determination by radioreceptor assay

To the Editors:

The association between intrauterine exposure of female fetuses to diethylstilbestrol and the later occurrence of uterine, cervical, and vaginal anomalies, as well as clear cell adenocarcinoma of the cervix and the vagina, is well documented.[1-3]

Since the diethylstilbestrol molecule is structurally related to the clomiphene molecule, the presence of clomiphene or clomiphene metabolite during estrogen-sensitive organogenesis may interfere with normal development of those organs, resulting in the previously mentioned diseases. Studies with carbon 14–labeled clomiphene citrate have shown that clomiphene is excreted principally in the feces.[4] An average of 51% of the administered dose was excreted after 5 days. The appearance of carbon 14 in the feces 6 weeks after administration suggests that the remaining drug and/or metabolites are slowly excreted from a sequestered enterohepatic recirculation pool.

Such studies do not necessarily indicate that the radiolabeled compounds measured are biologically active, that is, capable of binding to the estrogen receptor in estrogen target cells. Binding to the estrogen receptor is thought to be a requirement of a compound that has estrogenic and/or antiestrogenic activity.

A simple radioreceptor assay suitable for measuring clomiphene and its active metabolites simultaneously in serum of patients undergoing clomiphene treatment was developed by our group.[5] The assay is based on the competitive replacement of radiolabeled estradiol in the estrogen receptor of the rat uterus by the active ligands present in the serum.

The amount of ligand extracted from the serum was expressed as estradiol-binding equivalent, that is, their equivalent in pycograms of estradiol.

To exclude the contribution of endogenous estrogens, three volunteer women with amenorrhea with no endogenous estrogens were selected for the study.

After the usual treatment scheme of clomiphen, estradiol-binding equivalent concentration rose and reached its highest levels (ranging from 2000 to 7000 pg/ml) about 12 hours after the last drug was administered. Thereafter estradiol-binding equivalent levels declined gradually.

On day 54 after cessation of clomiphene therapy, no clomiphene and/or metabolites (estradiol-binding equivalent equaled pretreatment levels <80 pg/ml) were found in the patient's sera.

In conclusion, the observation that on day 54, the assumed time of estrogen-sensitive organogenes in the conception cycle, no estrogen receptor–binding ligands were detected is reassuring regarding possible late adverse effects of the drug. However, differences in the metabolic clearance rate of the drug in euestrogenic and pregnant women could not be excluded. Furthermore, since the drug has only been used for 20 years, final conclusions on the long-term safety to the offspring will have to be delayed until sufficiently large surveys on postpubertal offspring have been concluded.

Spontaneous fetal seizures in utero

To the Editors:

The recent report by Conover et al. (Antenatal diagnosis of fetal seizure activity with use of real-time ultrasound. AM J OBSTET GYNECOL 1986;155:846-7.) of the first two cases of spontaneous fetal seizures in utero has reinforced my belief that such seizures occur more frequently than would appear from a review of the literature. I describe a case of what I believe is intrauterine fetal seizures causing a characteristic artifact on direct fetal scalp electrode cardiotocography.

A 25-year-old primigravida had labor induced by prostaglandin E_2 vaginal pessary because of moderate preeclampsia at term. During labor she was sedated with chlormethiazole and was given an epidural analgesic. A normal infant weighing 3.1 kg was easily delivered with Neville-Barnes forceps because of delay in the second stage of labor. The Apgar score was 7 at 1 minute and 8 at 5 minutes. Throughout labor the fetal heart was monitored by direct scalp electrode cardiotocography with a single helix scalp electrode and a Hewlett-Packard 8030A cardiotocograph. The fetal

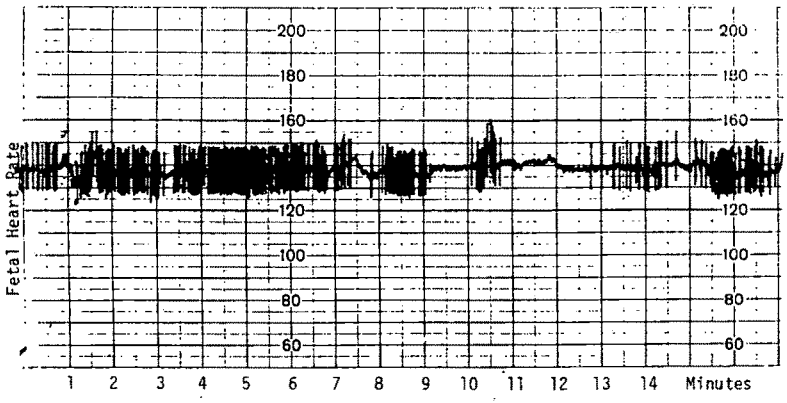

Fig. 1. Fetal heart rate tracing.

heart tracing was normal, with intermittent episodes of artifacts resembling a railway line (Fig. 1). At 24 hours of age, the infant started to have seizures that required phenobarbitone, paraldehyde, chloral hydrate, and eventually diazepam to control. A computerized tomography scan performed on the fourth day of life showed extensive infarction of the right cerebral hemisphere. A full investigation did not reveal any other etiologic factors. The infant has a left flacid hemiparesis at 2 months of age.

I believe that the artifacts seen on the cardiotocograph represent intrauterine fetal seizures. My reasons are as follows.

There was no evidence of perinatal asphyxia, which is the common cause of early neonatal convulsions. The forceps delivery was straightforward, and the infant's condition at birth was good.

Intrauterine fetal seizures would be expected to cause intermittent electrical discharges of an amplitude in the range of 100 to 500 μV. This is within the sensitivity range of the Hewlett-Packard 8030A (30 μV to 3 mV). Furthermore, when transcutaneous electrical nerve stimulation is used for pain relief during labor, a burst of high-frequency electrical discharge between electrodes attached to the maternal skin causes the same artifact on direct cardiotocography.

The episodic and recurrent nature of these artifacts form a pattern that is consistent with fetal convulsions and is unlikely, in my opinion, to be from poor contact of the scalp electrode.

I have seen one other case of cardiotocographic artifacts under similar clinical circumstances and an almost identical appearance of the infant's brain on the computerized tomography scan. Unfortunately, that cardiotocograph has been lost.

Human ovarian oxytocin and steroid hormones

To the Editors:

We read with great interest the article by Dawood and Khan-Dawood (Human ovarian oxytocin: its source and relationship to steroid hormones. AM J OBSTET GYNECOL 1986;154:756-63) that describes the source of human ovarian oxytocin and its relationship with steroid hormones. The authors conclude that oxytocin is present in and is probably produced by the human corpus luteum.

This conclusion is, however, clouded by the analytic procedures used in these investigations. For example, in the figure showing reverse-phase high-pressure liquid chromatography (Fig. 1, p. 757) and in the Methods section, no mention is made of the sensitivity of their high-pressure liquid chromatography system. How many micrograms (or nanograms) of authentic oxytocin were used as the standard? The authors also fail to report the wavelength used in their detector. This is important because detection wavelength determines sensitivity to some extent. This aspect is vital in view of the fact that a peak of absorbance apparently corresponding to oxytocin appears on the high-pressure liquid chromatography tracing from the corpus luteum extract. Is this peak oxytocin? It seems very unlikely because the corpus luteum only contains, at most, 30 ng/gm of luteal tissue (as shown in Fig. 3, p. 758) at its peak during the luteal phase; the quantities of peptides (i.e., authentic oxytocin) used to calibrate high-pressure liquid chromatography systems are usually measured in micrograms.

As a sidelight, ref. 9, which refers to the synthesis of oxytocin from labeled precursor, should be ref. 8. In the Swann et al. paper (ref. 8), no tritium-leucine was used; sulfur 35–cysteine was the label employed.

Reply

To the Editors:

We are pleased that Drs. Auletta and Flint are interested in our paper "Human ovarian oxytocin: its source and relationship to steroid hormones" (AM J OBSTET GYNECOL 1986;154:756-63). For this study, reverse-phase high-pressure liquid chromatography was performed on a 3.9 by 30 mm Bondapak C_{18} column (Waters Associates, Milford, Mass.) by gradient elution with 0.1% trifluoroacetic acid and water (solvent A) and 70% acetonitrile, 29.9% water and 0.1% trifluoroacetic acid (solvent B) at a flow rate of 1 ml/min. The elution positions of both the standard oxytocin and the corpus luteum extract were monitored by absorption at 214 nm. Under these conditions, the minimum amount of oxytocin standard that can be detected is 20 ng at a AUFS (absorbance units full scale) setting of 0.01. The chromatogram shows that a peak of oxytocin standard (250 ng) at a retention time of 14.86 minutes and the quantity of radioimmunoassayable oxytocin in the corpora lutea extracts that was chromatographed are equivalent to 320 ng of oxytocin. The extract of tissue that was chromatographed was a pool from 12 corpora lutea. Each corpus luteum extract was first assayed by radioimmunoassay, and the extracts were then pooled and reassayed for oxytocin. Since the publication of this paper, we have obtained consistently similar findings with reverse-phase high-pressure liquid chromatography of extracts of our on-going corpora lutea collection. Therefore we are confident that the similar retention times and peaks obtained with the corpora lutea and the pure oxytocin standard represent oxytocin.

We agree with Drs. Auletta and Flint that ref. 9 referring to the synthesis of oxytocin from labeled precursor should be ref. 8 and that ^{35}S-cysteine and not ^{3}H-leucine was employed. We regret the typographic errors and thank Drs. Auletta and Flint for pointing them out.

Teen pregnancies

To the Editors:

Drs. Hollingsworth and Felice (Teenage pregnancy: A multiracial sociologic problem. AM J OBSTET GYNECOL 1986;155:741-6) cite decreasing teen birth rates to support their conclusions about teen pregnancy rates. The two are incomparable. Not all teen pregnancies result in birth—thousands end in abortion every day. This error in the article prohibits the authors from the conclusion that teen pregnancies are not increasing.

Table I. Pregnancy rate, abortion rate, and birth rate per 1000 women, ages 15 to 19 years, for all races, 1979 to 1983

	1980	*1983*
Pregnancy rate, age at outcome*	111.2	109.9
Abortion rate	42.9	43.5
Birth rate	53.3	51.7

*Includes estimated numbers of pregnancies ending in spontaneous abortions and stillbirths. These data present additional evidence that both pregnancy and birth rates have declined in teenagers.

Reply

To the Editors:

We thank Gregory R. Roush for his letter and comment that birth rates and pregnancy rates are not comparable. His observation is correct, and not all teen pregnancies result in birth.

In our paper we relied on public birth and census figures.[1]

Henshaw,[2] who used well-established estimate formulas for pregnancy rates, has recently reported that from 1978 to 1983, the pregnancy rates for nonwhite 15- to 19-year-old teens decreased whereas pregnancy rates for white teenagers have increased. Table I shows the decrease in pregnancy rate and birth rate from 1980 to 1983 with very little change in abortion rate. After rising during the 1970s, the adolescent pregnancy rate peaked around 1980 to 1981 and fell slightly in 1982 to 1983.

Have Liley charts outlived their usefulness?

To the Editors:

I read with great interest the article "Have Liley charts outlived their usefulness?" by Nicolaides et al.

that appeared in the July issue (Am J Obstet Gynecol 1987;155:90-4).

Rather than relying on amniotic fluid specimens to manage high-risk, Rh-sensitized pregnancy, they advocate the use of fetal hemoglobin levels. On the several occasions when I heard Dr. Liley present his material during visits to the United States, I seem to remember him always saying that the tables were not good before the twenty-eighth week. In his original 1963 article "Errors in the Assessment," when he presented his table of probabilities the table began at week 28 of gestation and concluded in week 40 of gestation. Dr. Liley said to me on at least one occasion that there was not enough experience in his controlled studies to make predictions before 28 weeks and not after 40 weeks.

Over the years several authors have persisted in extending Liley's diagonal lines back in space so that predictions could be made without the outcome of pregnancy at 22, 24, or even 26 weeks. This is just not possible without someone repeating Dr. Liley's classic experiments.

Reply

To the Editors:

I agree with the comments of Dr. Duhring. The points are repeatedly stressed in the paper that reviewed the methodology used by Dr. Liley and stresses that in the third trimester amniocentesis and interpretation of delta optical density at 450 nm values by the Liley method have proved to be reliable. However, the findings of the paper suggest that in the second trimester of pregnancy, fetal blood sampling is the only accurate method of assessing the severity of fetal anemia.

Hypertensive diseases of pregnancy: Nulliparity, primiparity, multiparity, and gravidity

To the Editors:

In an otherwise fine article (Hypertensive diseases of pregnancy and parity. Am J Obstet Gynecol 1986; 154:1044-9) on hypertensive diseases of pregnancy and parity, Gleicher et al.,[1] while criticizing the vague and "somewhat" arbitrary terminology of hypertensive diseases, fail to accurately designate their two subsets of patients, presumably those who have not been delivered of a fetus or fetuses who have reached the stage of viability and those who have. If parity is the variable in question, then the two groups of gravidas who are compared are nulliparous and parous women and *not* primiparous and multiparous women. Likewise, nulliparous and *not* primiparous patients make up the bulk of patients with "true" preeclampsia. Parous patients include those who are para 1 or primiparas and para 2 and greater or multiparas.

Further confusion about the terminology is suggested in the introduction where primigravid women (excluding multigravid nulliparas) are compared with multiparas, the proverbial apples and oranges dichotomy. Finally, after parity is described as the distinctive study variable, the authors conclude that "*gravidity* is the single best option in the differential diagnosis of hypertensive diseases during pregnancy."

Is *parity* the significant variable?

Reply

To the Editors:

We appreciate the interest in our paper but have to disagree with Reamy's well-meant criticism of our terminology. Patients included in this study were already delivered when their status was analyzed. In fact, weight determinations of newborn infants probably represented the most important outcome variable of this study. To classify women who had given birth to their first child as "primiparous" and others as "multiparous" consequently appears correct and understandable to the reader.

Pemphigus in pregnancy: A reevaluation of fetal risk

To the Editors:

We are much impressed with the paper by Ross et al. (Pemphigus in pregnancy: A reevaluation of fetal risk. Am J Obstet Gynecol 1986;155:130-3) on fetal risk in pregnancy with pemphigus vulgaris. Our experience with a live baby affected with neonatal pemphigus prompted us to review the pertinent literature.[1]

Not surprisingly, we concur with Ross et al. regarding their conclusion that the fetus of a mother with pemphigus is at risk of intrauterine death (23% stillbirth rate). Their considerations were also raised by us, namely, that high dose of corticosteroids either causes placenta insufficiency or encourages overwhelming infection in the fetus and thus intrauterine death. We also believe that it is unlikely that pemphigus vulgaris is the cause of stillbirth.

One way to curb fetal risk in cases of pemphigus vulgaris in the pregnant woman can be the repeated use of plasmapheresis. This should be considered when the woman in question either: (1) requires a high dose of corticosteroids, (2) suffers from any opportunistic infection, (3) has a high titer of circulating pemphigus antibodies, or (4) when the fetal well-being profile (biophysical and biochemical) is low.[2] Plasmapheresis was suggested in the past for cases of pemphigus vulgaris,[3] but not advocated for pemphigus during pregnancy. This might be a useful measure until the completion of pregnancy instead of high-dose corticosteroid treatment and might presumably decrease the fetal risk in these precarious cases.

The cause of uterine softening in pregnancy

To the Editors:

It was with great interest that we read the article of Dr. Munsick (Dickinson's sign: Focal uterine softening in early pregnancy and its correlation with the placental site. AM J OBSTET GYNECOL 1985;152:799-802) with regard to his experience about the site of implantation of the placenta as observed during artificial terminations of the pregnancy. In his experience, the site of softening corresponded with that of the implantation of the placenta in 88% of the cases.

Our pertinent experience rests in 150 observations based on cases of normal pregnancy between the sixth and twentieth weeks of gestation. When the softening was widespread, we attempted to establish the site of maximum softening. We found that the softening was most frequent in the fundal area of the uterus (Table I).

In 68 cases we used real-time ultrasound examination for the determination of placental localization. In this regard, our findings are similar to those of Dr. Munsick: The sites of implantation and softening were identical in 54 instances (79.42%) and differed in six cases (8.82%). In the remaining eight cases (11.76%), we could not identify a specific area of softening. Of the latter cases, the site of implantation was the posterior uterine wall in seven patients in whom it appears that it is more difficult to appreciate the occurrence of uterine softening than elsewhere. In one instance we found the uterus rather contractile, a circumstance that hindered the accuracy of the observation.

Table I. Distribution of the sites of uterine softening in pregnancy

Site of softening	*No. of cases*	*%*
Fundus	40	26.67
Right uterine wall	36	24.00
Left uterine wall	31	20.67
Anterior uterine wall	11	7.33
Posterior uterine wall	6	4.00
Undecided	26	17.33
Total	150	100.00

The fact that in approximately 80% of our cases the site of softening coincided with that of placental implantation, appears to support the concept of Csapo and Pulkinen[1] concerning the differing consistency of the myometrium in areas adjacent to or remote from the site of placental implantation, a phenomenon leading to functional asymmetry.

Intrapartum electronic fetal monitoring efficacy

To the Editors:

On the basis of a review of seven randomized controlled clinical trials, Dr. Thacker concludes in his report (The efficacy of intrapartum electronic fetal monitoring. AM J OBSTET GYNECOL 1987;156:24) that electronic fetal monitoring is not a useful procedure for all women in labor. He states "while the randomized controlled clinical trial is the most powerful tool available to assess a clinical practice such as electronic fetal monitoring, even this tool has limitations."

In at least one report cited by Dr. Thacker, electronic fetal monitoring was used as a screening test to determine which patients were high risk and needed electronic fetal monitoring.

However, what is most significant are the two reports not discussed by Dr. Thacker. In the report by Ingemarrson et al., "Impact of routine fetal monitoring during labor on fetal outcome with long-term follow-up (AM J OBSTET GYNECOL 1981;141:29), the authors concluded, "The improved short-term and long-term fetal outcomes seem to be largely a result of routine fetal monitoring with all its implications for obstetric and neonatal management; the significant reduction in neurological sequelae, even after correction for other

changes in obstetric routines supports this suggestion." In the report by Erkkola et al., "Analysis of intrapartum fetal deaths: their decline with increasing electronic fetal monitoring" (Acta Obstet Gynecol Scand 1984;63: 459) the authors concluded that when 95% of all vaginal deliveries received electronic fetal monitoring in the fourth consecutive 3-year period of the study, intrapartum fetal deaths (IFDs) were 0.3/1000 compared with 1.7/1000 in the first 3-year period of the study when only 9% of labors were monitored electronically. The authors add, "our material gives strong support to the numerical speculation of Quilligan and Paul that in an obstetric service with 3000 deliveries annually, by undertaking 100% monitoring, 6 IFDs might be avoided."

As a practicing clinician caring for the life, health, and welfare of mothers and their fetuses in the labor and delivery suite and not at a distance in an office chair, I still remember the occasions, fortunately few, of being called by the labor room nurse to come attend what turned out to be an intrapartum fetal death in a mother not receiving the benefit of continuous electronic fetal monitoring in labor, whereas I have never experienced to date an intrapartum fetal death in a mother who was the beneficiary of continuous electronic fetal monitoring in labor. Therefore, on the basis of reported studies and clinical experience I conclude that the benefits of electronic fetal monitoring in all labors far outweigh either the risks of electronic fetal monitoring and/or not using electronic fetal monitoring, as seems proved so far at least for the prevention of intrapartum fetal deaths and fetal neurologic sequelae. The prevention of these two dire conditions, one fatal and the other disabling, is enough for me to justify that the beneficial cost-efficiency of routine electronic fetal monitoring in labor adds up in the black on the financial balance sheet and in the physical and emotional health and welfare of the specific persons involved and society in general.

Reply

To the Editors:

In my paper on the efficacy of electronic fetal monitoring, I assessed the effectiveness of electronic fetal monitoring as an intrapartum screening tool.[1] I presented a systematic method for evaluating the evidence from seven randomized controlled clinical trials and concluded that benefits might be limited to the reduction of neonatal seizures and that the data did not demonstrate that electronic fetal monitoring is a useful screening procedure for all women in labor. Dr. Fribourg is a concerned clinician who believes that the routine use of electronic fetal monitoring is important to "the health and welfare of mothers and their fetus[es]." To support his contention, he cites his clinical experience and two reports from the clinical literature.

The approach in my report was based on epidemiologic evidence. Because efficacy of a clinical procedure can best be measured in randomized controlled clinical trials, I focused on the data from randomized controlled clinical trials to assess the effectiveness and safety of routine electronic fetal monitoring. The two reports Dr. Fribourg cited are not randomized controlled clinical trials and for that reason were not included in my analysis. Taken together, the seven randomized controlled clinical trials do not demonstrate a significant decrease in intrapartum deaths atributable to routine electronic fetal monitoring. As indicated in my paper, the Dublin trial[2] shows that routine electronic fetal monitoring is associated with a significant decrease in neonatal seizures but not a decrease in serious neurologic sequelae. Two subsequently published reports on clinical trials designed to assess electronic fetal monitoring support my conclusions.[3, 4]

As a medical epidemiologist, I use epidemiology as a tool to address problems that routinely confront clinicians such as Dr. Fribourg. Since many of our health care practices are being assessed with epidemiologic studies, it is important that such studies be critically reviewed. Clinicians can then interpret and use this information on the basis of their experience in patient care. Hopefully, by combining epidemiologic evidence and clinical understanding, we can maximize women's and infants' health.

Previous cesarean delivery and trial of labor

To the Editors:

The basic premise stated in the first paragraph of the article by Finley and Gibbs (Emergent cesarean delivery in patients undergoing a trial of labor with a

transverse lower segment scar. AM J OBSTET GYNECOL 1986;155:936), "that a trial of labor be allowed only in labor and delivery units with continuous fetal monitoring, 24-hour blood banking, and an operative start-up time of 30 minutes implies an increased intrapartum risk," is wrong. The aforementioned recommendations are taken from a February 1985 publication from the Committee on Obstetrics: Maternal and Fetal Medicine of the American College of Obstetricians and Gynecologists.

However, *Standards for Obstetric-Gynecologic Services* (6th ed. Washington, DC: The American College of Obstetricians and Gynecologists, 1985:29-30) sent to Fellows of the College in June 1985 states, "Any facility providing obstetric care, however, should have the following minimum services available," and then proceeds to itemize 11 requirements, which include all those mentioned by Drs. Finley and Gibbs.

Therefore it seems that in fact patients with a previous cesarean undergoing a trial of labor are considered to be at the same risk as those patients in labor without a previous cesarean, which is contrary to what the authors have written, and that the same minimal level of obstetric care is required by (or *recommended for*) all patients.

This is a personal communication of its author and is in no way is to be construed as representing either Kaiser Permanente or Southern California Permanente Medical Group.

Reply

To the Editors:

We appreciate the comments and criticisms provided by Dr. Fribourg. The intent of our initial paragraph was to restate the obvious—preconceived risks are associated with a trial of labor in the minds of many clinicians. The existence of such preconceptions is made obvious by the current low frequency of trial of labor in patients with a prior low transverse cesarean section (8%) and by the fact that only 46% of hospitals allow trial of labor.[1] We did not, however, mean to imply that the Committee on Obstetrics: Maternal/Fetal Medicine or the American College of Obstetrics and Gynecology attaches such increased risks to a trial of labor. The existence of such communication by the Committee on Obstetrics: Maternal/Fetal Medicine, however, demonstrates a response to such preconceived risks.

As described in our second paragraph, it was our intent to address the hazards associated with a trial of labor in a defined clinical setting. We believe that our data concur with the flavor or Dr. Fribourg's letter—a trial of labor in selected patients does not place them at undo risk. It is our hope that such data will allow for an increase in the percentage of appropriate candidates being proffered a trial of labor in the future.

HELLP syndrome

To the Editors:

In the report by Sibai et al. (Maternal-perinatal outcome associated with the syndrome of hemolysis, elevated liver enzymes, and low platelets in severe preeclampisa-eclampsia. AM J OBSTET GYNECOL 1986; 155:501-9), the prognosis with a "true" HELLP syndrome in preeclampsia was associated with a poor maternal-perinatal outcome.

What is confusing is Dr. Sibai's conclusion that he could work with these mothers using the steroids and wait 48 to 72 hours. This is a catastrophic dilemma. Even in his 1985 article he stated that there was no justification for conservative management of severe preeclampsia.

To improve gestational age we delay the delivery of babies who are sick. The babies have a higher incidence of growth retardation and a higher incidence of low Apgar scores. The steroid therapy did not improve the pregnancy outcome.

Once the diagnosis of severe preeclampsia is made, the only therapy would be to get the patient delivered. This was Dieckmann's dictum in the early 1950s, and it is true today.

With the aid of Dr. Weinstein's HELLP syndrome and the use of serial platelet counts, we can arrive at an earlier diagnosis and the degree severity of the disease process.

Our conclusion would differ from that of Dr. Sibai in that steroid therapy has no place in the treatment of severe preeclampsia. The time delay is more detrimental to the mother than the benefits of increase in gestational age.

Reply

To the Editors:

I would like to thank Dr. Gerace for his interest in our article.

Dr. Gerace questioned the value of using steroids in patients with severe preeclampsia, and he recommended immediate delivery of all such patients, irrespective of gestational age. He cited some references (Dieckmann and Weinstein), and yet he supplied none of his own data. The data regarding the benefits from steroids in preeclampsia are confusing, but a benefit for such therapy has been reported by several authors (see references in our article). Our data did not demonstrate such a benefit in our population. Hence, the recommendation in the closing remarks of the paper was for patients with minimal laboratory findings (not true HELLP) as reported by others. The benefits of using steroids in preeclampsia will be the subject of an upcoming report from this institution. (Gonzalez and Sibai. In preparation.)

OB/GYN

WANTED: Obstetrician/Gynecologist, Board Certified or eligible physician to join existing 3 member OB/GYN Department in 22 member multi-specialty group practice in the Lakes Region of central N.H. Position offers an outstanding professional, financial, and life-style opportunity. Respond with C.V. to Alan Awrich, M.D., Laconia Clinic, 724 Main Street, Laconia, NH 03246.

PERINATOLOGISTS

Illinois, Chicago - Lutheran General Hospital is seeking two Perinatologists for an excellent opportunity in direct patient care, teaching and clinical research. Lutheran General is a 700-bed teaching hospital affiliated with the University of Illinois College of Medicine in Chicago. It is a designated tertiary care center with 3600 deliveries annually and has an active maternal transport service of over 200 a year. The Obstetrics and Gynecology Department has a residency program, and subspecialists in Gynecology/Endocrinology and Gynecology/Oncology. There is a 36-bed neonatal NICU with five neonatologists and a fellowship program. There is also a large referral service for genetic counseling and prenatal diagnoses, and more than 750 genetic amniocentesis are preformed annually. We have recently opened a large Perinatal Tertiary Center office.

The hospital is located in an attractive northwest suburb of Chicago. We offer a competitive salary with a generous incentive plan and an excellent benefit package.

Please send your curriculum vitae to:

Orlando, FL 32806

OB/GYN GENERALIST

Pennsylvania Hospital seeks 2 board certified or eligible obstetrician/gynecologists. One position is available as of January 1, 1988, the other as of July 1, 1988. Responsibilities include resident and medical student education and active clinical practice. Appointment is at the assistant professor level. Applications from women and minority persons are especially welcome.

Pennsylvania Hospital is an affiliate of the University of Pennsylvania and is an affirmative action/equal opportunity employer.

Interested candidates should send a curriculum vitae and letter to:

Linda K. Dunn, M.D.
Department of Obstetrics and Gynecology
Pennsylvania Hospital
8th & Spruce Streets
Philadelphia, PA 19107

KAISER PERMANENTE

Good People. Good Medicine.

Maternal-Fetal Medicine

BC/BE Perinatologist wanted to join another subspecialist in a large multispecialty HMO located in the San Francisco-Oakland Bay Area.

Responsibilities include clinical service in two tertiary referral centers with 6,000 deliveries/year; consultations in high risk patients, genetic testing, ultrasound, resident teaching, and perinatal outreach programs. CVS experience desirable.

Each institution with full NICU capabilities with total of six neonatologists. Oakland facility with approved residency program (12 residents), oncologist, endocrine-infertility subspecialists, Level II Ultrasound capabilities and antenatal testing unit.

Excellent benefits including competitive salary, malpractice insurance, medical and dental coverage, vacation and sick leave, pension and retirement programs. University affiliation and clinical research available.

Please write or call, including your curriculum vitae and three references:

Victor Chin, M.D., FACOG
Chief, Department of Obstetrics & Gynecology
The Permanente Medical Group, Inc.
280 West MacArthur Blvd.
Oakland, CA 94611
415 428-7340
or Lawrence Newman, M.D., FACOG
Perinatologist
415 428-7087

OBSTETRICIAN GYNECOLOGIST

Board eligible/board certified obstetrician/gynecologist wanted to join expanding Ob/Gyn Department of Southboro Medical Group, Inc. Southboro Medical Group is a multispecialty group practice located 30 minutes of Boston in the affluent town of Southboro, Massachusetts. There are currently two full time board certified ob/gyn's in the department who are very busy and hope to eventually have two additional ob/gyn's to share the practice. This position offers a generous salary, the potential for incentive bonus during the first two years, and excellent fringe benefits including paid malpractice insurance. Please contact:

Michael S. Robertson, M.D.
Southboro Medical Group, Inc.
P.O. Box E1
Southboro, MA 01772.

Obstetricians/ Gynecologists

St. Margaret's Hospital for Women is seeking several Board Certified/Board Eligible Obstetricians/Gynecologists to join our expanding group private practice in affiliation with the Hospital. St. Margaret's is one of the largest Catholic specialty hospitals in OB/GYN, and a major perinatal and neonatal center, and is affiliated with Tufts University School of Medicine.

Excellent salary and benefits are offered. Interested candidates should respond with curriculum vitae to: Linda Caliga, President, St. Margaret's Hospital for Women, 90 Cushing Ave., Boston, MA 02125.

An equal opportunity employer employer

ST. MARGARET'S HOSPITAL FOR WOMEN

PERINATOLOGISTS

Three full-time positions are available as perinatologists in Maternal-Fetal Medicine in the Department of OB/GYN, U.C. Davis Medical Center, Sacramento. Applicants should be Board eligible or certified in OB/GYN and must have successfully completed subspecilaty training in Maternal-Fetal Medicine with subsequent Specialty Board eligibility and/or certification. Applicants must demonstrate experience and competence in teaching effectiveness and research related activities. Applicants must demonstrate experience in prenatal diagnosis, ultrasound and genetics.

Responsibilities include inpatient and outpatient case management, surgery and procedures specific to high risk obstetrics, participation in teaching activities with residents, interns and medical students, development and/or participation in research activities and involvement in University and Hospital committees.

Send curriculum vitae and five references to:

R. Jeffrey Chang, M.D.
Chairman, Department of Obstetrics and Gynecology
University of California, Davis, Medical Center
1621 Alhambra Boulevard, Suite 2500
Sacramento, California 95816

The final date for receipt of appplications is "Open until filled, but not later than April 1, 1988"

The University of California, Davis is an equal opportunity, affirmative actior employer.

FACULTY POSITION

Department of Obstetrics and Gynecology
University of Massachusetts Medical Center

We are seeking board certified Obstetricians/Gynecologists to join our University Group of Obstetricians. Full time faculty positions offer excellent opportunities in resident education, active clinical practice and research.

Academic level will be in accordance with experience and achievement. Along with competitive salary, benefits include; membership in a multi-specialty Group Practice Plan, paid professional liability insurance, state and group retirement plans, health, dental, life, and disability insurance.

Located in Central Massachusetts, the area provides year round recreational opportunities, a variety of residential styles and abundant educational/cultural options.

Interested candidates should send a curriculum vitae and letter to:

Richard E. Hunter, M.D.
Chairman, Ob/Gyn
University of Mass. Medical Center
55 Lake Avenue North
Worcester, MA 01655

GYNECOLOGIC ONCOLOGIST
DIVISION OF GYNECOLOGIC ONCOLOGY
UNIVERSITY OF WASHINGTON

Full time position available for a Board certified or Board eligible gynecologic oncologist to be based in a large community hospital near Seattle in a program affiliated with the University of Washington School of Medicine. Full academic appointment commensurate with experience. Must be eligible for or have Washington state licence.

Send Curriculum Vitae or CONTACT:

David C. Figge, M.D.
Director, Gynecologic Oncology
University Hospital (RH-20)
University of Washington
Seattle, WA 98195

AN EQUAL OPPORTUNITY EMPLOYER

OBSTETRICS AND GYNECOLOGY

The Department of Obstetrics and Gynecology at the **University of Wisconsin/Madison** is seeking 2 faculty members, 1 for general Obstetrics/Gynecology and 1 for the General Gynecology Service.

The General Obstitrician/Gynecologist will act as consultant to a staff-model HMO. For the faculty member position, colposcopy and laser experience are highly desirable. Both positions involve supervision and teaching of residents and students, the general practice of Obstetrics and Gynecology within the departmental practice plan, and some administration. Opportunity for clinical research available. Academic rank and salary commensurate with experience. Inquiries to: **C.B. Martin, Jr., MD, Department of Obstetrics & Gynecology, H4/654, Clinical Science Center, 600 Highland Avenue, Madison, WI 53792.**

University of Wisconsin Hospital & Clinics

The University of Wisconsin is an Equal Opportunity/Affirmative Action Employer.

Faculty Position in Maternal-Fetal Medicine

The Department of Obstetrics and Gynecology at Wright State University School of Medicine invites applications for a full-time faculty position in Maternal-Fetal Medicine combined with the position of Medical Director of a regional perinatal care center.

Primary duties will include the teaching of medical students and residents, the pursuit of scholarly activities, and the medical administration of the perinatal center which includes the obstetrical unit and the labor and delivery suite.

Applicant qualifications include the M.D. degree, board certification in obstetrics and gynecology, licensability to practice Medicine in Ohio, completion of a fellowship in maternal-fetal medicine, board eligibility or certification in maternal-fetal medicine, and extensive training and experience in perinatal medicine and administration of health services. Academic rank and salary will be commensurate with qualifications and professional experience. Please send curriculum vitae and the names of three references to: John J. Halki, M.D., Ph.D., Chair and Program Director, Department of Obstetrics and Gynecology, Wright State University School of Medicine, 1 Wyoming Street, Dayton, OH 45409.

The Wright State University School of Medicine is an Affirmative Action and Equal Opportunity Employer.

All applications received by November 30, 1987 will be considered; if the position is not filled therefrom, applications will be considered as received until the position is filled.

POSITION AVAILABLE

Our medical group is actively engaged in the practice of gynecology and obstetrics in the metropolitan Detroit, Michigan area. As a result of growth, we are prepared to add one additional associate.

This opportunity provides compensation and fringe benefits considerably greater than you might otherwise expect. In addition, permanent participation in our group is anticipated.

If you are interested in joining our group, we would be pleased to discuss these matters with you in greater detail. Your inquiry will be kept in confidence if you so desire. Please call collect or direct replies to:

Roger M. Kushner, D.O.
27301 Five Mile Road
Redford, MI 48239
Telephone: (313) 535-8484

21-and 28-day regimens

ORTHO-NOVUM 777 Tablets

norethindrone/ethinyl estradiol TRADEMARK

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

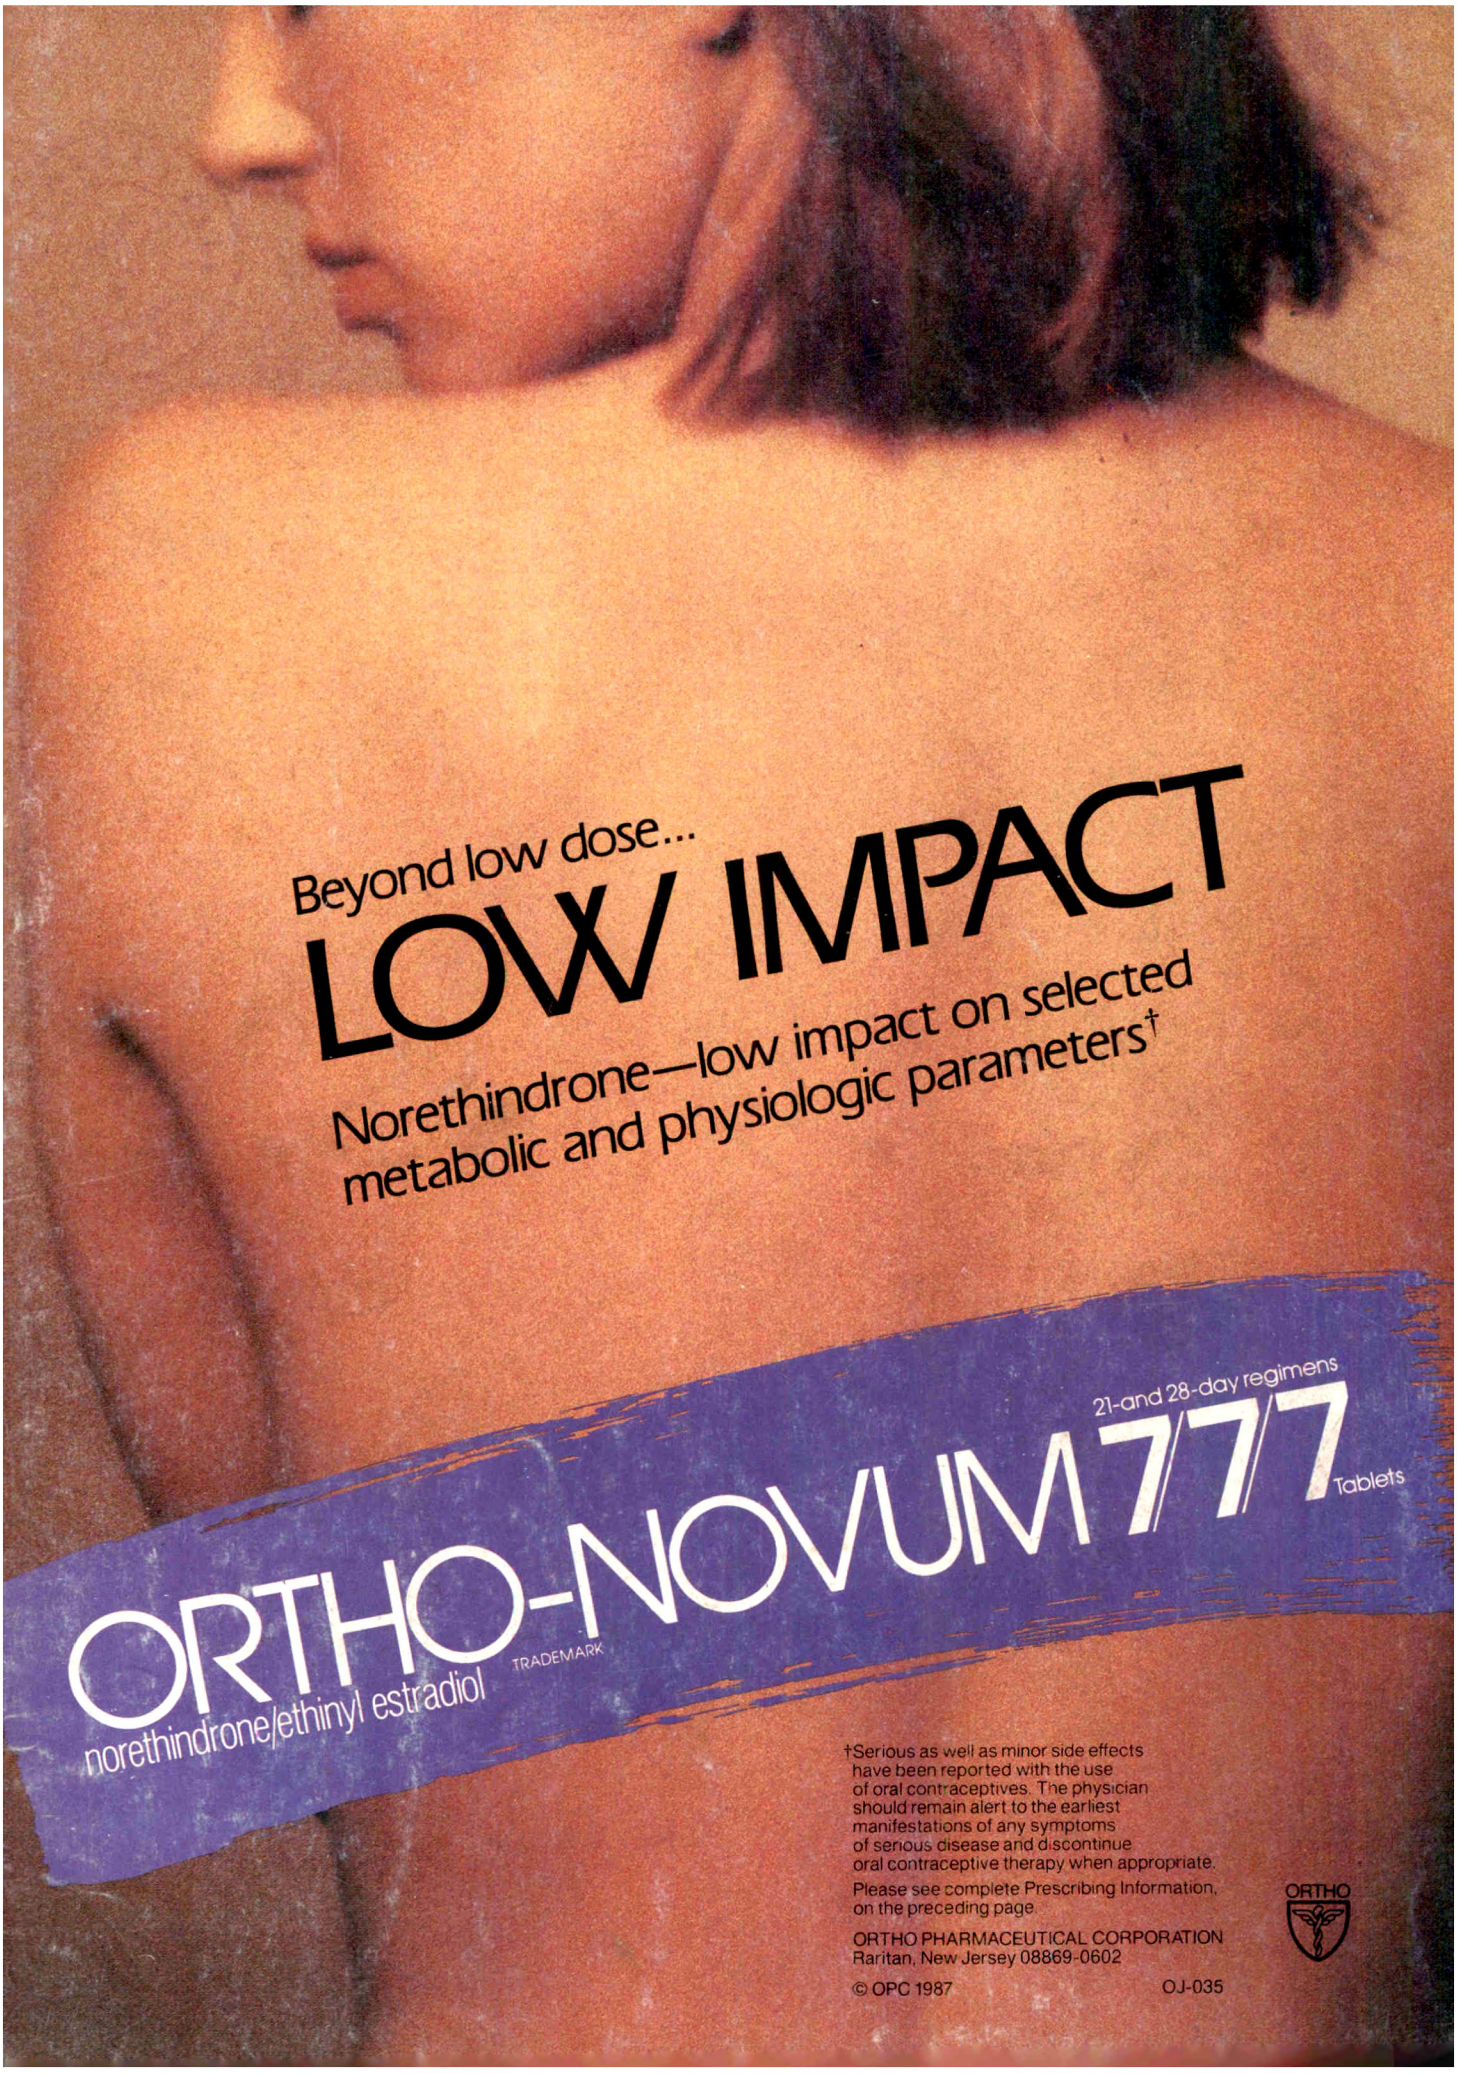
IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen.

CONTRAINDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Oral contraceptive tablets may cause fetal harm when administered to a pregnant woman. Oral contraceptive tablets are contraindicated in women who are pregnant. If the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus (see WARNINGS, No. 5). 8. Benign or malignant liver tumor which developed during the use of oral contraceptives or other estrogen-containing products.

WARNINGS



Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers. A prospective study conducted in Great Britain estimated that former users have a risk for all cerebrovascular disease 2.6 times greater than that of nonusers. This risk remained elevated for at least six years after last oral contraceptive use. A prospective study conducted in the United States found that past use of oral contraceptives was associated with increased risk of subarachnoid hemorrhage, the relative risk being 5.3. There was also some evidence from this study that the degree of risk may be related to duration of oral contraceptive use. **MYOCARDIAL INFARCTION:** An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. A study suggests that some increased risk of myocardial infarction in oral contraceptive users persists following discontinuation of oral contraceptives and that the degree of the residual risk is related to the duration of the past use. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory disease mortality may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. 4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations and use of oral contraceptives with high hormonal potency and age over 30 years may further increase the woman's risk of hepatocellular adenoma. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. Cases of hepatocellular carcinoma, although rare, have been reported in women taking oral contraceptives. Retrospective studies conducted in the United States and Britain report an increased risk of hepatocellular carcinoma in oral contraceptive users, particularly with increased duration of use. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin, griseofulvin, and tetracycline. **DRUG/LABORATORY TEST INTERACTIONS:** The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

PART 1: ORAL CONTRACEPTION

Introduction

Leon Speroff, M.D.
Cleveland, Ohio

A decade's worth of evidence has helped quiet the storm of controversy that once surrounded the use of oral contraceptives (OCs). Our message to each other as clinicians and to our patients can now be a very positive one: The low-dose OC formulations available today not only offer nearly perfect efficacy but are also safer than ever before.

This message is bolstered by a series of reports presented in the first half of a Contraception Plenary Session at the XII World Congress of Fertility and Sterility in Singapore, October 28, 1986, the proceedings of which appear in this publication. The international experts who participated in this symposium accurately assessed the epidemiologic claims of an association between contraceptive steroid use and deep vein thrombosis, myocardial infarction, and stroke, and went on to indicate that there is no case for an OC–breast cancer link. The optimism of their epidemiologic reassessment is mirrored by current clinical evidence that the new low-dosage formulations represent a major step forward in enhancing the safety of hormonal contraception. The data presented at this symposium indicate that low-dose triphasic OCs exert no significant impact on metabolic and hematologic indices thought to predict cardiovascular risk.

We hope that the proceedings of this symposium will provide clinicians with reassuring new perspectives on the state of the art in oral contraception as well as with practical guidelines for patient care.

From Case Western Reserve University.

Contraception: An overview

Jürgen Hammerstein, M.D.
Berlin, West Germany

In this century, paramount progress has been made in many areas of medicine, not least in the field of contraception, with landmarks such as the introduction of intrauterine contraceptive devices (IUDs), hormonal contraceptives (OCs), and laparoscopic sterilization. The general optimism of the 1960s about overcoming the problems of global overpopulation with these new tools has subsequently been replaced by growing concern about the risks of contraception in general and of OCs especially. It was not before the 1980s that the benefit-risk balance of hormonal contraception turned out to be much more favorable than was formerly suspected. The wide variation from country to country in the prevalence of contraceptive methods has economic, political, religious, sociological, educational, and legal rather than medical reasons. Former misjudgments have led to a ban on valuable tools such as the sequential regimen or the use of 17-acetoxyprogestogen analogues as components in OCs, or to a ban on the licensing of depot progestogens in some countries but not in others. The recent decision of U.S. firms to cease production and sale of IUDs for legal reasons is unique and hopefully will not be imitated elsewhere. Just after the introduction of oral contraception, tremendous inventive dynamics led to the discovery of several new contraceptive principles. Most of these have reached the stage of clinical application and are being used satisfactorily, at least in some parts of the world. Later contraceptive concepts are still in the stage of experimentation and no breakthrough appears to be directly ahead. If contraception means more than just meeting individual wants—if it is also to be an instrument for handling the increasing problems of overpopulation—then much more must be done to deepen our knowledge of reproductive physiology, to popularize efficient means of contraception, and to make them available to everyone. Otherwise, all efforts to improve health standards throughout the world according to the "WHO Global Strategy for Health for All by the Year 2000" will be in vain. (Am J Obstet Gynecol 1987;157:1020-3.)

Key words: Contraception, intrauterine contraceptive devices, hormonal contraception, laparoscopic sterilization, benefit-risk balance, global overpopulation

In this century, we have been witness to paramount progress in many areas of medicine and not least in the field of contraception, with landmarks such as the introduction of the first practical intrauterine contraceptive device (IUD), the Gräfenberg ring, in the 1920s; the elaboration of the first oral contraceptive (OC) by Pincus, Garcia, and Rock in the 1950s; and the development of laparoscopic tubal sterilization in the 1960s.

As a result of these major advances, the belief became widespread in the scientific community that it should be possible to overcome the problems of overpopulation on our globe by means of these new tools. I well remember the great optimism of various experts around 1970 that new developments in fertility control would replace oral and intrauterine contraception within a decade or so. Unfortunately, this prophecy was not fulfilled, as everyone knows. Progress has been slow, no innovative breakthrough has taken place, and there have been several setbacks. What then is the situation of fertility control today?

From the Division of Gynecologic Endocrinology, Sterility, and Family Planning, Department of Obstetrics and Gynecology, Klinikum Steglitz, Free University of Berlin.

Patterns of use

From recent literature three major conclusions concerning the prevalence of modern methods of family planning worldwide may be drawn (Table I).[1, 2] First, sterilization has become most popular, which is true for either sex; second, the use of OCs has not increased during the last decade; and third, apart from China where more than two thirds of all IUDs are worn, the prevalence of intrauterine contraception appears to be decreasing rather than increasing in most countries.

The disparity in use prevalence of family planning methods between regions of the world, countries, and even cultural subgroups within countries is striking and has no counterpart elsewhere in medicine. For example, oral contraception is the preferred method of contraception in western Europe, as well as in various other countries. Intrauterine contraception is most popular in China, as already mentioned. Sterilization is the predominant means in the United States and India, whereas the traditional barrier and "natural" methods, backed up by induced abortion, have the highest prevalence in such different countries as the USSR and Japan.

Also the percentage of women who just do not use any kind of contraception despite urgent need differs

FRG = Federal Republic of Germany.

widely from country to country. Thus in India 68% of women at risk are not covered by modern measures of contraception.[1] This lack of contraceptive responsibility is, however, true not only for people living in the developing world but also, to a minor degree, for those in developed countries, with an estimated 30% of women not taking advantage of efficient contraceptive methods. This percentage may be much higher in special subgroups. For example, 50% of the more than 1 million teenagers in the United States who become pregnant involuntarily every year have never used contraception before their first conception.

That acceptability of contraceptive measures may develop in divergent directions can be derived from a comparison between the use rate of OCs in the United States and the Federal Republic of Germany over the years. Concurrent with the first campaign against oral contraception in 1970, there was a slight setback in the use of OCs in the United States. The most drastic drop in OC use rate occurred in the mid-1970s, when the first reports of a causal association between OC use and myocardial infarction became known. Thereafter, the popularity of hormonal contraception in the United States never recovered, with the use rate having remained below 10% for the last several years. Similar campaigns in the Federal Republic of Germany, initiated by the media for scientific or sometimes ideological reasons, failed to have any major influence on the OC use rate, which has been stable at around 30% for 14 years.

Divergent developments have also taken place in other countries. For example, there was a time when no fewer than 45% of all Dutch women between 15 and 44 years of age were using hormonal contraceptives. This is equivalent to about two thirds of all women in the reproductive age group who actually need and/or use fertility control. In Japan, at the opposite extreme, OCs are not yet officially permitted. In this country the use rate of ovulation inhibitors never exceeded 3%.

Contraceptive prevalence is also changing with age. The situation in El Salvador and Thailand may be considered exemplary in this respect.[2] Oral contraception is of utmost importance for younger women but is replaced later in reproductive life by other methods, namely, by female sterilization.

Nonmedical influences

It can be taken for certain that nowadays scientific information on the state of the art in contraception, as well as practical instruction on the various methods used in family planning, are available to anybody who asks. Therefore, the wide variation from country to country in the prevalence of contraceptive methods

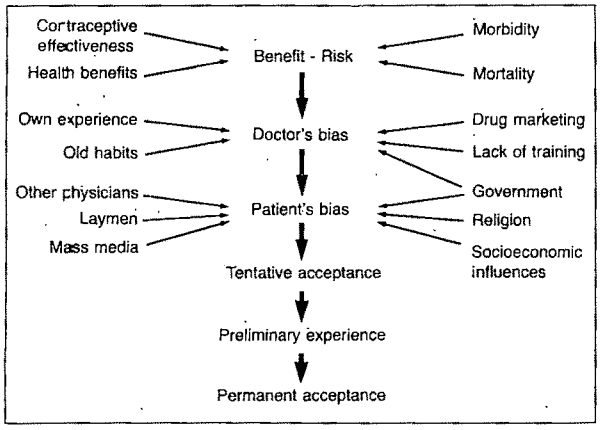

Fig. 1. The decision-making process: for or against the pill.

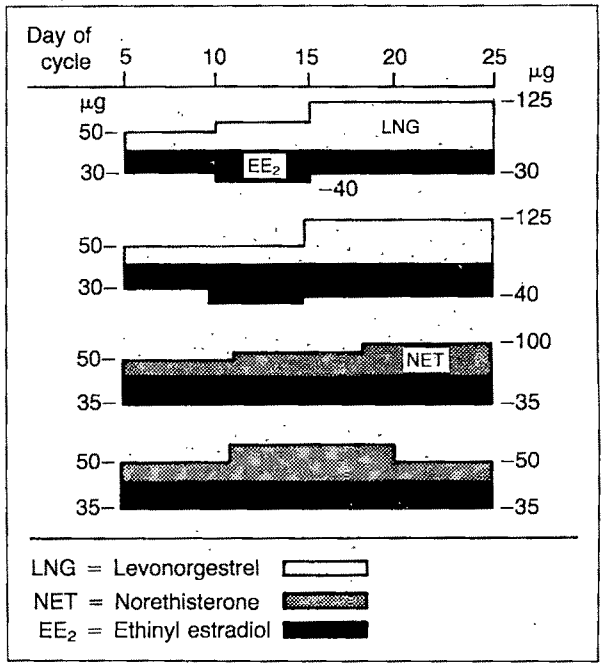

Fig. 2. Triphasic formulations presently available in the Federal Republic of Germany: Theme and variations.

must have economical, political, religious, sociological, cultural, and/or legal rather than medical reasons. Some of the grounds why proper medical counseling in this field is often biased are shown in Fig. 1. Socioeconomic and governmental influences are of highest importance in this respect, but drug marketing also plays some role.

The government impact arouses special concern, since decisions made by drug regulatory authorities are not always wise, and misjudgments will prevent persons from taking advantage of the progress of contraception, as has happened several times in the past. One such example is the withdrawal of all progestogens with a pregnane structure from oral contraception because of the wrongly interpreted breast tumor incidence in the beagle dog in the course of long-term toxicologic experiments. Revision of this more-than-15-year-old decision is mandatory, all the more since the 17-acetoxyprogestogens, in contrast to the estranes and gonanes, are devoid of any influence on lipoproteins.

Experience with the removal of the sequential formulations from the drug market in some countries has been quite similar: An increase in endometrial carcinomas had been observed only with one special preparation that contained the very weak progestogen dimethisterone for 5 days only. This regimen was thus equivalent to unopposed estrogen treatment, which notably can cause this type of tumor when given over long periods of time. The same has not been observed with any of the other sequential formulations. Nevertheless, they all had to be withdrawn from the market by decree in some countries.

To mention still one other example of misjudgment, which remains the secret of the Food and Drug Administration, is why depot progestogens are not permitted to be used as contraceptives in the country where they were developed. Although there are stringent medical indications to use them, in many places their benefits are withheld from the population without scientific justification.

Late in 1985, U.S. firms stopped the production and sale of IUDs for legal reasons. This is a completely new way of bringing progress to nought, leaving people with still fewer contraceptive alternatives than before. Hopefully, this step will not be imitated elsewhere.

New developments

In view of such retrograde progress, it is good to know of promising advances in the field, as was the case just after the advent of oral contraception and the rediscovery of the IUD. At that time, tremendous inventive dynamics led to the development of quite a few new contraceptive principles. Most of them, such as the minipill, depot progestogens, postcoital interception, subdermal implants, and vaginal rings (the latter two filled with progestogens), have since reached the state of clinical application and are being used satisfactorily at least in some parts of the world.

Whereas all of these new contraceptive principles were inaugurated before 1971, none of the innovative projects that were started after this date appears far enough advanced to come into general use soon, as discussed in the second part of this symposium.

Several minor changes in the mode of sex hormone application have been proposed. Although none of them is as important as the true innovations already mentioned, some have become quite popular, such as

the sequential and the step-up regimens. Others, like the once-a-month pill, the once-a-month injection, and the once-a-week pill, are used only in a few countries. Several additional modifications of oral contraception are already almost forgotten, as, for example, the Chinese paper pill, the French midcycle pill, and the British tri-cycle pill regimen.

The least spectacular but nonetheless most important line of recent development in oral contraception has been the worldwide endeavor to reduce the OC risk potential (Table II). This has led to a remarkable decrease in the hormone content of the pill, to the introduction of new contraceptive steroids, and to changes in the estrogen/progestogen ratio. In the latter respect, the triphasic regimens, of which several types are available (Fig. 2), have gained increasing attention in recent years. By these various means, OC-induced metabolic disturbances, which are often enough the starting point for side effects and serious complications, have been definitively reduced.

If contraception means more than just meeting individual needs, if it is also to be an instrument for handling the increasing problems of overpopulation, then much more must be done here and now to deepen our knowledge of reproductive physiology, to popularize the efficient means of contraception, and to make these methods available to everyone. There is no time to lose—it is less than 5 minutes til midnight. If the young generation, which constitutes nearly 50% of the population in some developing countries, behaves as their parents did after starting sexual life and reproductive activity, the problem of overpopulation will become disastrous. All developmental progress would be negated, with malnutrition, pauperization, and epidemic diseases being inevitable consequences. Then the optimistic "WHO Global Strategy for Health for All by the Year 2000" would not make sense any longer. We all should try to prevent this development, even if this means swimming against a torrential stream.

Hormonal contraception: Benefits versus risks

Joseph W. Goldzieher, M.D.
Houston, Texas

Epidemiologic studies, chiefly in English and U.S. populations, have generated concern regarding cardiovascular hazards associated with the use of oral contraceptives (OCs). A detailed analysis of these data suggests, however, that such studies have serious methodologic flaws. For example, the clinical diagnosis of deep vein thrombosis may be incorrect up to 50% of the time, rendering statistical analysis meaningless. The known cardiovascular risks of cigarette smoking may be amplified by OC use, but nonsmokers probably do not have an increased risk. Further, a number of studies in developing-world countries do not yield evidence of increased cardiovascular risks of OC use. Abnormal levels of serum lipids appear to affect cardiovascular (that is, myocardial infarction) risks in Western populations. Whether normalization of these levels improves the outlook is not entirely certain. The hormonal components of OCs are known to affect serum lipids, raising concern about possible long-term consequences. Newer low-dose OC formulations (such as triphasics) do not cause changes in serum lipids and therefore eliminate this putative risk. (Am J Obstet Gynecol 1987;157:1023-8.)

Key words: Hormonal contraceptives, benefits, risks

The effects of steroid hormones are ubiquitous, influencing as they do a great variety of endocrine and nonendocrine systems. Nowhere is this of greater clinical and epidemiologic importance than in the case of the estrogenic and progestational hormones used in contraceptive formulations, which were being used by upward of 50 million women around the world at the beginning of the present decade. In keeping with the magnitude of this usage, there is no class of drugs that has generated a larger literature on the possibilities of adverse reactions. In the space allotted to this article,

From the Department of Obstetrics and Gynecology, Baylor College of Medicine.

it will not be possible to discuss the well-known hormonal effects of estrogens and progestational compounds, nor can one address the question of contraceptive efficacy, its origin, and the influence of external factors on its maintenance. Additionally, the establishment of an association between a drug and a rare adverse reaction (let alone proof of a causal relationship) is an issue in itself, challenging as it does the applicability of the commonly used techniques of epidemiology. This problem has been addressed with increasing concern by many investigators including my associates and myself[1-3]; although they cannot even be summarized here, it will be advantageous to bear in mind the uncertainties inherent in epidemiologic investigations in contrast to studies that are assessed by the known and tested criteria of experimental research.

The question of adverse effects is viewed quite differently in the case of an agent used to treat disease than in the case of one used to control fertility, even though the impact of unwanted, uncontrolled fertility may ultimately have a greater effect on our future than did all the epidemics of the Dark Ages. Moreover, the cultural and religious implications of fertility control add a dimension, not amenable to scientific logic, that places such concerns in an entirely different context.

In a status report, entitled "Oral contraceptives in the 1980s,"[4] no fewer than 713 references were cited, even though injectable and implantable delivery systems for contraceptive steroids were excluded from the review. It is evident, then, that important effects of contraceptive steroids on vitamins, other nutritional components, and energy systems (carbohydrate, protein, fat metabolism), on immunologic and related phenomena (for example, the decrease in first attacks of rheumatoid arthritis), and on the central nervous system, urinary tract, and cutaneous structures cannot be addressed at this time. Because of their importance in the medical as well as in the public mind, effects on the cardiovascular system and on oncogenesis will be the focus of attention.

Cardiovascular effects

Blood coagulation. There is an enormous literature on changes in blood coagulation factors observed in users of oral contraceptives (OCs) and on the existence and possible consequences of a "hypercoagulable state." Mammen[5] has admirably summarized this literature as follows: "Many conflicting test results have been reported, probably reflecting in part the technical difficulties . . . in assay systems. None of the data obtained seems to be specific for OC users . . . and none was found uniformly in all takers . . .. At this time, it is not known whether oral contraceptives do or do not trigger the hemostasis system to develop a thrombosis or by which mechanism they could trigger the event."

This is the first of two problems that becloud the question of the relationship of thromboembolic disease to the use of contraceptive steroids. The second is the reliability of the epidemiologic data that report a statistically significant association between deep vein

Table II. Deaths from cardiovascular disease by age, smoking status, and oral contraceptive use*

thrombosis and contraceptive steroid use. The purely technical problems complicating such epidemiologic research have been discussed at length elsewhere,[1-3] and this controversial issue is not likely to be settled in the near future. However, another methodologic issue of overriding importance has become apparent in the last few years. The application of sophisticated methods, such as intravenous radiolabeled fibrinogen, Doppler ultrasound, and impedance plethysmography, has shown that the clinical diagnosis of deep vein thrombosis (on which all epidemiologic studies have relied) is *grossly inaccurate*. Rates of failure to make the diagnosis clinically (compared with instrumental diagnosis) range from 22% to 78%, and the rate of false positive clinical diagnoses ranges from 25% to 83% (Table I). In one interesting study,[21] a positive clinical diagnosis was incorrect in 69% of cases—except when the patients were known to be OC users, in which case the clinical diagnosis was incorrect in 83%. Obviously, epidemiologic arithmetic based on such faulty information is useless, and as a result, we are completely unenlightened as to whether there is an association, causal or otherwise, between deep vein thrombosis and contraceptive steroid usage.

Myocardial infarction and stroke. On the other hand, retrospective case/control studies of myocardial infarction and stroke indicated a significant "relative risk" associated with use of OCs that was not likely to arise from diagnostic error. Prospective studies appeared to confirm the hazard. Then a confounding factor—smoking—was discovered. When the data were adjusted for this known cardiovascular hazard, the risk was found to be almost exclusively in heavy smokers. The difference in relative risk between nonsmoking pill users and nonusers of the same age group was *no greater than could easily occur by chance.*

Recent mortality statistics from the Royal College of General Practitioners, London, bear out this finding (Table II). The data base of this study is now very large: 138,700 women years in controls, 99,000 in current pill users, and 84,800 in former pill users. The small number of deaths (64) in this large population is noteworthy. The number of deaths in the various age groups is so small that most biometricians would be very cautious in drawing inferences about increased risk. Nevertheless, the association with smoking is inescapable.

Studies[22,23] carried out on this side of the Atlantic are also reassuring. The Walnut Creek Study,[23] sponsored by the National Institutes of Health, included 16,638 women (28% of them pill users) followed up for a total of 107,000 woman years. The investigators concluded, ". . . in a population of young adult healthy white middle class women the risks of OC use appear to be negligible."

Even more recently, Porter et al.[22] summarized data on 36,428 women years of pill user experience. They reported seven cases of stroke, six of them in nonusers, and no myocardial infarcts. They also found no relationship between estrogen dose and the incidence of clinically diagnosed thromboembolic disease.

When the supposed increased risks for myocardial infarction and stroke were first publicized, there was immediate and appropriate pressure to decrease the OC dose to the minimum that maintained contraceptive effectiveness, on the assumption that the hazards were dose related. A succession of formulation changes occurred, in the course of which the dose of the estrogen component, either ethinyl estradiol or mestranol, dropped from about 50 μg to the minimum effective dose, about 30 μg. (The chance of contraceptive failure with the low-dose formulations inevitably increases in the event of irregular drug intake or decreased drug bioavailability. Fortunately, the problem has turned out to be less serious than expected, and the effectiveness statistics on these formulations are astonishingly good.[24]) Some revisionists now claim that the current decreased estimate of cardiovascular hazards associated with oral contraception is due to the downward shift

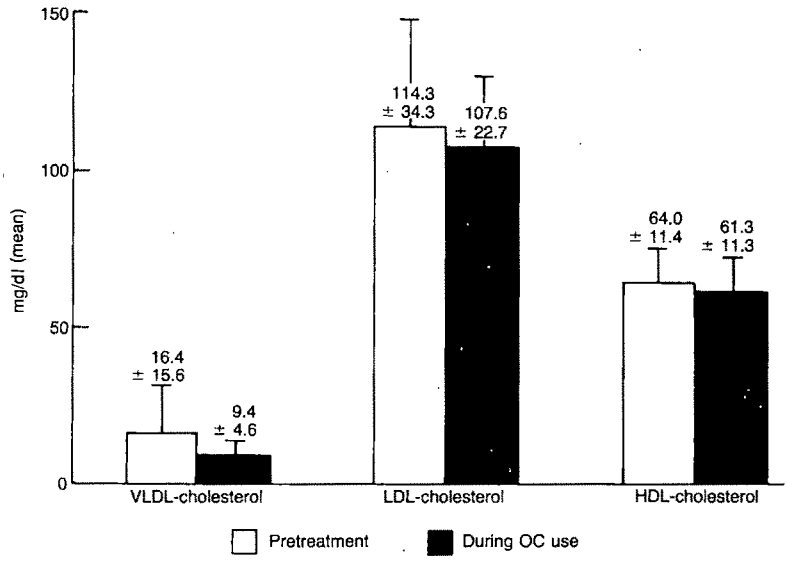

Fig. 1. Lipoprotein fractions with a levonorgestrel-containing triphasic OC. (Reproduced with permission from März W, Romberg G, Gahn G, Gross W, Kuhl H, Taubert HD. Effect of oral contraceptives upon serum lipoprotein pattern in healthy women. In: Rolland R, ed. Advances in fertility control and the treatment of sterility. Lancaster, England: MTP Press, 1984:99-106.)

in estrogen dosage. However, a number of studies show that this is not the case. In Denmark, for example, all pill users were abruptly switched to a low-dose pill in 1974. Stroke and myocardial infarction mortality statistics did not change, indicating either that lowering the dose does not decrease risk or that there was no measurable risk in the first place.

Blood lipids. Currently, there is appropriate concern about the possibility of ultimate cardiovascular effects from the influence of contraceptive steroids on blood lipids. Long-term studies on myocardial infarction seem to indicate that relatively minor changes in blood lipids can have significant effects on the incidence of myocardial infarction. For example, in one study a 19% reduction in coronary heart disease risk accompanied an 8% decrease in total serum cholesterol or an 11% decrease in low-density lipoprotein cholesterol.[25] Small increases in high-density lipoprotein cholesterol were also associated with a slight decrease in coronary heart disease risk. However, there is no unanimity among cardiovascular researchers as to the prognostic significance of various lipoprotein levels. (A recent British study even opined that high-density lipoprotein cholesterol levels were not predictive.[26]) Moreover, the expected advantages of altering lipoprotein levels in a "beneficial" direction are not convincingly demonstrable as yet; it would be beneficial for gynecologists to recognize the uncertain state of this research and not to take dogmatic statements by epidemiologists too seriously.

We must also recognize that the epidemiologic data on coronary risk are derived from a heavily male population; further, the women who sustained infarcts have been in the postmenopausal years. Kannel of the Framingham Study admitted several years ago that there had not been a single myocardial infarction in a premenopausal woman in that study. It is clear that such data cannot simply be extrapolated to the much younger and substantially different population of OC users; nevertheless, these data certainly justify current efforts to modify OC formulations so as to have as little effect as possible on plasma lipids (Fig. 1). While the current literature describing the effect of specific formulations on the lipoproteins and lipids is not entirely consistent, it is clear that reduction of dosage, change in proportion of the two steroids, and the choice of one progestational agent over another can modify or eliminate altogether the effect of hormonal contraceptives on plasma lipids and lipoproteins.

Neoplasms

Many types of neoplasia, especially cancers of reproductive or related organs, are affected by steroid hormones. Both endogenous and exogenous hormones can influence the observed incidence and prognosis of cancer. Thus, when steroid contraceptives were introduced, there were expressions of concern that these agents might either initiate or promote oncogenesis. Two decades of research have produced reassuring data, in spite of the long lag period inherent in carcinogenesis.

Endometrial cancer. Except for experience with one particular sequential OC (now withdrawn), the epidemiologic data are uniformly in agreement in estimating

a substantial decrease in endometrial cancer, the degree of benefit apparently increasing with duration of use. For those who have used steroid contraceptives for a period of 2 years or longer, there seems to be a (persistent) reduction in incidence of about 50%, resulting in an estimated 2000 fewer hospitalizations per year for this disease in the United States.[27]

Ovarian cancer. With respect to ovarian cancer, steroid contraceptive use appears to have the same type of protective effect as pregnancy. Ovarian cancer has a poor prognosis: Even with the best treatment, the 5-year survival rate is only 20%. In the United States, it accounts for 6% of all female cancer deaths. The decrease in ovarian cancer was estimated at about 50% in steroid contraceptive users, and the effect persisted for more than 15 years after first use. In the United States, birth control pill use averted about 1700 cases in women aged 20 to 54 in 1979 alone.

Cervical cancer. The effect of hormonal contraceptives on cervical cancer is unclear. There is much to suggest that cervical neoplasia is a virus-induced disease. It is clearly related to certain characteristics of sexual activity, particularly age at first coitus and number of partners. Epidemiologic studies that do not control for these factors[28] appear to be an exercise in futility.

Benign breast disease. Benign breast disease appears to be favorably influenced by steroidal contraceptive use: Despite more intensive medical surveillance, breast biopsies are performed half as often in contraceptive steroid users as in nonusers.[27] Women who use steroid contraceptives have a somewhat decreased risk for fibrocystic disease as a whole; the higher the progestational dosage, the lower the risk. This makes good endocrinologic sense. Patients whose biopsy specimens showed atypia, and controls had similar degrees of steroid contraceptive usage, while cysts or papillomatosis were half as common in users as in controls.[29]

Breast cancer. Numerous studies of steroid contraceptive use and breast cancer have failed to show a statistically significant association, except for one study[30] that was heavily criticized on methodologic grounds and was essentially discounted by a special Food and Drug Administration workshop on this subject. The recently published joint Centers for Disease Control/National Institutes of Health study—a monumental piece of work—also failed to uncover any risk.[31,32]

Melanoma. A 1977 report from California raised suspicions about an association of melanoma with steroid contraceptive use.[33] However, a number of studies in other localities have failed to confirm this association.

Benign liver tumors. An interesting situation arose with respect to benign liver tumors, which are extremely rare but present the risk of spontaneous rupture and hemorrhage. One careful case/control study showed a very strong increase in relative risk associated with increased duration of steroid contraceptive use.[34] Further studies were hampered by the rarity of these cases. More recently, a histopathologic study from the Armed Forces Institute of Pathology pointed out that one type of hepatic tumor (fibro lamellar) typically occurs in the age group likely to be using steroid contraceptives and that this age-related bias probably accounts for the statistical association.[35]

Pituitary tumors. Finally, we turn to the question of pituitary tumors and steroid contraceptive use—a problem that arose from the observation of so-called "postpill amenorrhea" and its association with pituitary microprolactinomas. A recent multicenter study of pituitary adenomas failed to establish a statistical association with contraceptive steroid use,[36] and another report[37] clarified the situation even further: In women with prolactinomas who had used these steroids for contraception, the relative risk was 1 (that is, a chance association), whereas in women who had used steroid contraceptives for regulation of menstrual problems the relative risk was 7.7 (95% confidence limit 3.7 to 17), clearly indicating the preexisting nature of the alleged association.

In the last analysis, the effects of contraceptive steroids on various organ systems are important (aside from intrinsic scientific interest) in the achievement of the desired therapeutic result as balanced against the hazards of their use. However, any benefit/risk assessment extends far beyond the limits of medical/scientific considerations and must include psychosocial, economic, and demographic considerations. The incredibly time- and effort-consuming studies that have been sponsored by the developed countries are highly relevant and justifiable in the context of their health systems; one should, however, question their relevance and applicability to the developing world, where maternal mortality is an overriding concern and postpartum thrombosis or myocardial infarction in women is almost unknown.

Metabolic effects of oral contraceptives

Ulysse J. Gaspard, M.D., Ph.D.
Liège, Belgium

Combination oral contraceptives (OCs) are probably not an independent risk factor for cardiovascular disease but through their metabolic actions, may partly amplify the effects of known risk factors for cardiovascular disease. This review of the literature and our own data indicate that use of high-dose, progestogen-dominant OCs induces a potentially atherogenic lipoprotein profile (high low-density lipoprotein–cholesterol:high-density lipoprotein–cholesterol ratio), mostly attributable to the antiestrogenic action of the progestogen content of these OCs. In contrast, lower-dose combination OCs with reduced amounts of progestogens and slight estrogen dominance, either monophasic or multiphasic, produce strikingly fewer adverse effects on lipoproteins. Moreover, use of low-dose, as opposed to high-dose, OCs results in almost unchanged glucose tolerance, marginally increased or unchanged insulin and glucagon responses to glucose, and probably unchanged levels and activity of peripheral insulin receptors. Further in-depth studies of low-dose OC formulations are mandatory to ascertain reduced metabolic risk of these OCs. (Am J Obstet Gynecol 1987;157:1029-41.)

Key words: Combination oral contraceptives, risk-factors for cardiovascular disease, high-dose and low-dose progestogens, atherogenic lipoprotein profile, glucose tolerance

Numerous epidemiologic studies have indicated an increased frequency of cardiovascular disease, such as deep vein thrombosis and thromboembolism, ischemic heart disease and myocardial infarction, thrombotic and hemorrhagic strokes, and hypertension, in oral contraceptive (OC) users.[1] However, if other well-known risk factors for cardiovascular disease such as smoking, hypertension, increased age, diabetes, and hyperlipidemia are already present, the frequency of ischemic heart disease and stroke is markedly increased.[2,3] Accordingly, there is currently some debate as to whether the OC itself can be considered to be a primary risk factor or, rather, is an amplifier of the above-mentioned risk factors, making some women more vulnerable to cardiovascular disease.

Indeed, excess mortality in current and past OC users is essentially confined to women over the age of 35 who smoke. The Royal College of General Practitioners study reported significant excess mortality but other epidemiologic studies have not.[4] Further, Realini and Goldzieher[5] recently questioned and minimized a direct association between OC use and cardiovascular disease in a critical review of potential bias in these epidemiologic studies. Some observations suggest that, on the one hand, reducing the estrogen dose of combination OCs might appreciably decrease the incidence of venous thromboembolism[6] and that, on the other hand, reducing the progestogen content might decrease the incidence of nonvenous deaths (mainly from stroke and coronary heart disease).[7]

From the Department of Obstetrics and Gynecology, State University of Liège.

Laboratory findings suggest that both the estrogen and progestogen components of OCs correlate, often in a dose-dependent manner, with alterations in blood coagulation and fibrinolysis, the renin-angiotensin-aldosterone system, prostaglandins (particularly the prostacycline-thromboxane balance),[8] glucose tolerance,[9] and lipid and lipoprotein metabolism,[1] and even changes in vessel wall structure and function.[10] These metabolic effects of OCs could potentially cause such clinical problems as thrombosis and atherosclerosis.

Reducing the untoward cardiovascular side effects of OCs is essential since these drugs are designed for widespread use by healthy women and with minimum medical supervision. To achieve this goal, exclusion of women with high-risk factors as candidates for oral contraception has been advocated, and new OCs with reduced doses of both estrogen and progestogen have been formulated. This article summarizes some recent data concerning the effects of new low-dose OCs on lipoprotein and carbohydrate metabolism.

Design of experimental studies of metabolic effects of OCs

Lowering the doses of estrogen and progestogen in OCs also decreases the amplitude of fluctuations of biologic parameters in the subjects studied. In that respect, it seems reasonable to resort to prospective and preferably comparative and randomized, either straight or crossover, studies of healthy volunteers under the age of 35 who have none of the usual contraindications to OC use and who are carefully matched for age, race, anthropometric measurements, smoking, diet, alcohol consumption, and exercise habits. Con-

comitant study of a matched control group not taking OCs but submitting to the same investigation protocol would be ideal.

Moreover, as far as lipoprotein studies are concerned, fasting samplings are mandatory. Samples should be collected on two or more standardized occasions during control pretreatment cycles, preferably in the second phase (luteal phase), then serially collected during 6 to 12 months of OC treatment and again during the second or third posttreatment spontaneous cycles. Burkman et al.[11] insist on a 6- to 12-month study duration because of slowly ongoing fluctuations of apolipoproteins during therapy. However, Deslypere et al.[12] have reported that the effects of long-term use of OCs on lipids do not differ from those predicted from short-term (6-month) studies.

Studies of carbohydrate metabolism, currently performed mainly with the use of highly standardized oral glucose tolerance tests, should have a duration of at least 12 months and preferably 2 or more years.[13] They should also take into consideration circannual changes in glucose tolerance,[14, 15] which may misleadingly obliterate drug-induced metabolic fluctuations. Although retrospective studies of metabolic effects of OCs such as those reported by Wahl et al.[16] or insufficiently standardized results such as those of Wynn and Niththyananthan,[17, 18] for instance, are interesting because they are related to rather large and different populations of OC users, they are hampered by numerous biases. Heterogeneity of the study groups; uncertainty and heterogeneity concerning the nature, dosage, or even succession of OCs used; and drastically diminishing numbers of subjects during the course of the study (perhaps reflecting dropouts due to side effects) can deeply alter the meaning of the results and the value of comparisons between OCs.

Finally, fluctuations in the biologic results obtained in all these studies should be carefully analyzed in relation to the methodologic procedures used.[19] Although random, non–drug-induced fluctuations of some parameters may be statistically significant, they may be devoid of clinical meaning. For example, spontaneous variations of circulating lipid concentrations are generally estimated to be ± 10%, and accordingly statistically significant variations should be associated with fluctuations of absolute values by >10%.

Lipoprotein metabolism

Lipoprotein metabolism and atherosclerosis. In the plasma, cholesterol (C) and triglycerides are carried by five lipoprotein fractions: chylomicrons, very-low-density lipoproteins (VLDL), remnants, low-density lipoproteins (LDL), and high-density lipoproteins (HDL).

Transport lipoproteins for triglycerides are chylomicrons and VLDL, mostly originating from the small intestinal mucosa and the hepatocytes, respectively. It is noteworthy that apolipoprotein B is a major structural component of both types of particles. These triglyceride-rich lipoproteins are peripherally submitted to hydrolysis in the presence of extrahepatic lipoprotein lipase. Subsequently, glycerol and free fatty acids are delivered to peripheral tissues while these lipoproteins become remnant particles, partly removed from the circulation by the liver and partly progressively converted to LDL particles, rich in apolipoprotein B and C. In fact, LDL accounts for about 70% of circulating C and finally supplies this lipid to peripheral cells that possess high-affinity receptors for apolipoprotein B. In contrast, HDL particles, synthesized according to various processes and probably mainly originating as discoid particles (nascent HDL) from the liver, are rich in apoproteins A_1 and A_2. In a complex process of maturing to HDL_3 particles (the heaviest fraction of HDL), these lipoproteins intervene in the uptake of free C from peripheral tissues and other sources, its esterification by lecithin-C acetyl transferase, and subsequent transfer into the particle core. This HDL particle becomes a spherical, transformed HDL_2 lipoprotein rich in phospholipid and C (about 20% of circulating C). It is now strongly believed that HDL particles play a major part in the reverse transport of C from peripheral tissues to the hepatocyte and its subsequent excretion into the bile. Hepatic hydrolysis of HDL_2 phospholipids by endothelial hepatic lipase may contribute to this process, activate catabolism of HDL_2, and potentially generate some HDL_3 particles. More details on lipoprotein metabolism can be obtained in recent reviews by Miller,[20] Nikkilä,[21] and Heller.[22]

Greater knowledge of lipoprotein metabolism and its defects has enabled us to better understand the epidemiologic studies that describe a strong association between hyperlipidemia and the development of atherosclerosis and its multiple complications such as coronary heart disease.[23, 24] In most Western communities with high average consumptions of saturated fat and C, the prevalence and severity of ischemic heart disease in men as well as in women correlates well with different risk factors such as age, smoking, obesity, hypertension, and, of course, hyperlipidemia. In fact, a low HDL-C level, probably related to suboptimal reverse C transport, is an excellent predictor of subsequent heart disease (negative correlation with atherosclerosis) and is a better predictor of ischemic heart disease than are increases in LDL-C. An increase in LDL-C is involved in excess deposition of C in peripheral tissues and arterial walls (positive correlation of LDL-C and, to a lesser extent, of total C with atherosclerosis). Moreover, decreased levels of the subfraction HDL_2-C correlate better with the frequency and se-

verity of ischemic heart disease than do HDL-C or HDL_3-C.[25] The association between hypertriglyceridemia (mainly VLDL-triglycerides) and ischemic heart disease, although well recognized, is not totally a direct one. The cardiovascular risk inherent to hypertriglyceridemia appears to be partly associated with the precursor-product relationships between VLDL and LDL and the large inverse correlation between VLDL and HDL, confirming that VLDL concentrations are elevated in situations in which HDL levels are low.[26] It is thus understandable that the concentrations of HDL-C (and HDL_2-C), LDL-C, VLDL-triglycerides and of the ratios HDL-C:total C, HDL-C:LDL-C, or apolipoprotein A_1:apolipoprotein B[27] are epidemiologically important considerations in assessing the risk of atherosclerosis.

Effects of sex steroids on lipoprotein metabolism. After puberty and before the menopause, women with normal genital activity have lower median levels of VLDL and LDL but more HDL and a higher HDL:LDL ratio than do men of the same age. This sex difference in HDL concentrations is totally attributable to the increased HDL_2 subfraction in women.[20, 21, 27] The male:female coronary disease sex ratio is accordingly >1.0. The sex differential in secretion of the sex hormones accounts for the sex differential in lipoproteins, which, in turn, accounts for decreased atherogenic risk and increased longevity in women.[27]

Exogenous estrogens administered orally in high doses can increase liver synthesis and release of VLDL, triglycerides, and apolipoprotein B. They also increase plasma HDL concentrations, mainly by increasing the HDL_2 subfraction, HDL–apolipoprotein A_1, and plasma apolipoprotein A_1.[28] This rise in HDL levels could be partly related to a suppressive effect of estrogens on endothelial hepatic lipase.[21] The effects of estrogens on LDL concentration are controversial, but a decrease in LDL-C levels in postmenopausal women has been described.[21]

Natural progesterone given orally in replacement dosages (200 to 300 mg/day) is almost devoid of any effect on lipoprotein metabolism.[29] However, synthetic progestogens used in OCs are 19-nortestosterone–derived and, as such, display not only progestogenic but also androgenic and antiestrogenic actions capable of greatly altering lipoprotein metabolism. These steroids decrease plasma VLDL and triglyceride concentrations possibly by inhibiting hepatic synthesis and release of these compounds.[30] They can therefore antagonize the estrogen-induced rise in VLDL and triglyceride concentrations. LDL-C levels are increased by 19-nortestosterone–derived progestogens. In contrast, HDL and its subfraction HDL_2 are highly sensitive to the inhibitory action of these progestogens with antiestrogenic androgenic activity, which also reduce plasma apolipoprotein A_1 and potentially increase apolipoprotein B concentrations.[31, 32] By comparison, it is interesting to note that the use of androgenic anabolic steroids such as stanozolol in postmenopausal women is associated with increases in LDL-C, dramatic decreases in HDL-C (−50% from baseline) and in the most antiatherogenic subfraction HDL_2 (−85% from baseline), and less prominent decreases in HDL_3.[33] This experimental reversion of female to male lipid profile may increase the atherogenic risk of the subjects so treated.[27]

Combination OCs contain not only potent synthetic estrogens (ethinyl estradiol or mestranol) but also 19-nortestosterone-derived progestogens, such as the estranes norethisterone, lynestrenol, ethynodiol, ethynodrel, or dimethisterone, and the gonanes (levo)norgestrel, desogestrel, and, in the near future, norgestimate or gestodene. For this reason, it is of paramount importance to investigate whether these combination estrogen-progestogen OCs can alter lipoprotein composition and concentration and thereby the atherogenic risk of OC users.

Effects of high-dose combination OCs on lipoprotein metabolism. Until rather recently, most of the literature on the suspected alterations in lipid metabolism associated with OC use was mainly concerned with products containing 1 to 10 mg of a progestogen and 50 to 150 μg of either ethinyl estradiol or mestranol. Increased total serum triglycerides and less prominent fluctuations in total C levels (mainly small increases) were reported in users of these high-dose OCs.[34] More recent analyses[16, 31] have shown that those OCs that are overly progestational (that is, they contain high amounts of norethisterone, ethynodiol diacetate, or norgestrel and standard amounts of ethinyl estradiol or mestranol) induce increases >50% in median concentrations of total triglycerides when compared with concentrations in control subjects not using OCs. In addition, they cause a significant 24% increase in median concentrations of LDL-C, also accounting for the observed elevation in total serum cholesterol levels. Wahl et al.[16] reported no significant changes in HDL-C with high-dose OCs containing norethisterone or ethynodiol but a significant 20% decrease with a combination OC containing a high dose of norgestrel (500 μg). This study combined in the same group women taking combination OCs containing only 1 mg of norethisterone and women taking the higher dose of 2.5 mg, which may partly explain the small variation in HDL-C concentrations when compared with those of nonusers. However, Bradley et al.[31] noted a 20% decrease in HDL-C levels in subjects using OCs containing 2.5 mg of norethisterone, a result quite comparable to that obtained with the OC containing high

Table I. Tentative summary of different studies of effects of diverse combinations of ethinyl estradiol and norethisterone on lipoprotein metabolism

Type of OC (μg/day) and investigators	*Total C*	*Triglycerides*	*LDL-C*	*HDL-C*	*HDL_3-C*
EE 50 + NE 250[16,31]	Increased	Increased	Increased	Decreased	—

EE 35 + NE 750 (triphasic)[40]	Increased	Increased	Increased	No change	—
EE 35 + NE 500[41,42]	No change	Increased or no change	No change	No change	—
EE 35 + NE 400[43]	Increased	No change	No change	Increased	Increased

EE = Ethinyl estradiol; NE = norethisterone. Unless indicated otherwise, all changes are statistically significant relative to baseline levels or versus control group, as stated by investigators.

*Borderline statistical significance.

doses of norgestrel. In women using an even more progestogen-dominant combination (ethinyl estradiol, 30 μg, plus levonorgestrel, 250 μg, equivalent to norgestrel, 500 μg),* Wynn and Niththyananthan[18] reported significant decreases in HDL_2-C (−20% as compared with control value) and in HDL_3-C (−10%) concentrations. Such changes in HDL_2 and HDL_3 subfractions were not observed with combinations of ethinyl estradiol or mestranol, plus norethisterone, 1 mg, but these preparations are hardly comparable with the levonorgestrel-containing OC since they are much less progestogen dominant.

Other combination or sequential high-dose OCs are overly estrogenic, containing high amounts of ethinyl estradiol or mestranol and lower doses or shorter administration periods of progestogens such as, for instance, norethynodrel or dimethisterone. These preparations significantly increase median triglyceride concentrations by 80% and HDL-C levels by 35%, when compared with control values, whereas they only marginally and nonsignificantly increase LDL-C levels. These observations are in good agreement with the experimental results described above and indicate that intake of high-dose progestogen-dominant OCs is associated with moderate hypertriglyceridemia and a potentially more worrisome increase in the LDL-C:HDL-C ratio. In contrast, estrogen-dominant OCs, although associated with marked hypertriglyceridemia, also induce a more "favorable" decrease in the LDL-C:HDL-C ratio, thereby decreasing, at least theoretically, the atherogenic risk. However, these overly estrogenic preparations are associated with excess morbidity and mortality mainly as a result of venous thromboembolism[6] and endometrial adenocarcinoma, and they have been withdrawn from the market.

As summarized by Miller,[20] the estrogenic effects on lipoproteins are opposite to those of progestogens so that the net response to combinations of these agents is determined by the doses of the particular steroids employed. Since the most convenient estimate of atherogenic risk might be the ratios of total-C:HDL-C or LDL-C:HDL-C, an increase in these ratios by exogenous hormones should be viewed with suspicion.

The data of Wahl et al.[16] and Wynn and Niththyananthan[18] aroused considerable controversy because they implied that all 19-nortestosterone–derived progestogens did not act identically on lipoprotein metabolism and alleged that (levo)norgestrel induced a more atherogenic lipid profile in long-term users.

In addressing this important point, the following arguments must be considered: (1) The retrospective studies of these groups[16, 18] had numerous biases, mentioned earlier, that did not allow comparison of the highly progestogen-dominant preparation containing norgestrel with the equally progestational combination OCs. Moreover, the data of Wahl et al.[16] are at variance with the study of Bradley et al.,[31] which reported a decrease in HDL-C levels with norethisterone high-dose combinations similar to that seen when the norgestrel high-dose combinations are used. This decrease in HDL-C is in agreement with other studies, including a recent multicentered study conducted by the World Health Organization with OCs containing lower amounts of both these progestogens.[35] (2) With regard to the potency and nature of norethisterone and (levo)norgestrel, both compounds are derived from 19-nortestosterone and bind directly with high affinity to progesterone and androgen receptors and to sex hormone–binding globulin. The effects of these steroids on pharmacokinetic parameters and receptor binding and their in vivo activity (estrogenic, androgenic, progestogenic) are largely similar.[36] However, although norethisterone, norethisterone acetate, and ethynodiol diacetate are roughly equivalent in potency, levonorgestrel is approximately five to 20 times as potent, depending on the type of effect considered.[37]

As stated by Fotherby,[1] the effect of a low dose of a high-potency progestogen should be roughly the same

*This combination is not available in the U.S.

HDL_2-C	HDL-C/total C	HDL-C/LDL-C	Apolipoprotein A_1/ Apolipoprotein B	Apolipoprotein A_1	Apolipoprotein B
—	Decreased	Decreased	—	—	—

Increased*	No change	No change	—	—	—

as that of a high dose of a low-potency compound. This can be achieved with combination OCs containing (levo)norgestrel, since this progestogen powerfully inhibits gonadotropin secretion and hence gonadal function. The dose can therefore be drastically reduced in combination OCs without losing contraceptive effectiveness and the estrogen-progestogen balance of the preparation can be maintained because of its high antiestrogenic activity. In that way, the monthly dose of levonorgestrel in monophasic combinations has been reduced from 5.250 to 3.150 mg and even to 1.925 mg in a triphasic OC, which is a 63% decrease in progestogen content. In their study of the effects on lipoprotein metabolism of combination OCs containing degressive doses of levonorgestrel and accordingly characterized by moderately increasing ethinyl estradiol:levonorgestrel ratios, Larsson-Cohn et al.[38] concluded that ethinyl estradiol and levonorgestrel could be balanced so as to minimize undesirable effects on lipid metabolism. This also holds true for combination preparations with reduced doses of both ethinyl estradiol and norethisterone characterized by only minimal repercussions on lipoprotein metabolism (see below). (3) If there were a difference in "nature" between norethisterone and levonorgestrel, it would probably reside in a slight estrogenic activity of norethisterone already observable by its discrete keratinization effect on rat vaginal mucosa[36] and other estrogen-like effects.[39] Recent studies have shown that nonaromatizable metabolites of norethisterone exert typical estrogenic effects, such as induction of pituitary progestogen receptors.[39] No estrogenic metabolites of levonorgestrel have been identified so far, partly explaining why its antiestrogenic action is higher than that exhibited not only by norethisterone but also by desogestrel (see below). Its ability to depress plasma levels of sex hormone–binding globulin[36] and its ability to increase endothelial hepatic lipase activity[21] more so than other progestogens are able are two illustrations of its high antiestrogenic capability, which must be balanced by an adequate amount of ethinyl estradiol in combination OCs.

Effects of low-dose combination OCs on lipoprotein metabolism. Concern about increased cardiovascular risk in OC users has prompted the development of lower-dose combination OCs in the last decade. More studies of lipid metabolism, and particularly of lipid fractions that are potentially closely associated with atherogenic risk, have recently been conducted.

However, although many of these studies are prospective, they differ widely in protocol, duration of OC use, nature of the lipoproteins and lipid studied, statistical evaluation, and characteristics of the subjects tested. Consequently, all results must be interpreted with caution, keeping in mind that many of the changes recorded are small, although eventually statistically significant. They usually only reflect the summation of individual physiologic variations, especially if they are within the normal range. This caveat is particularly important in view of the small variations in lipid levels provoked by new low-dose OCs. A careful review of most of the recent studies devoted to that subject has been made by Fotherby.[1] Tables I (references 11, 16, 31, 35, 40-43) and II (references 16, 18, 31, 35, 38, 44-55) represent an attempt to synthesize the results obtained by different investigators and to indicate the statistically significant changes observed for relevant lipids and lipoprotein fractions and ratios, when there was a consensus among the studies. Otherwise, the discrepancy between results was noted.

Table I compares different preparations containing ethinyl estradiol and the estrane progestogen norethisterone, listed in order of decreasing steroid content. The roughly equal potency and metabolic effects of all progestogens of the estrane group (also including norethisterone acetate, ethynodiol diacetate, and lynestrenol) were taken into account.[37] Accordingly, attention was focused only on norethisterone-containing products. A comprehensive study by Powell et al.[56] of diverse preparations containing different doses of ethynodiol diacetate yields comparable results. In Table I, the high-dose combination OC containing ethinyl estradiol, 50 μg, plus norethisterone, 2500 μg, has been added for the sake of comparison with lower-dose preparations.

Table II compares preparations containing ethinyl estradiol and one of the gonane progestogens, levo-

Table II. Tentative summary of different studies concerning effects of diverse combinations of ethinyl estradiol and gonane progestogens on lipoprotein metabolism

Type of OC (μg/day) and investigators	*Total C*	*Triglycerides*	*LDL-C*	*HDL-C*	*HDL_3-C*

EE = ethinyl estradiol; LNG = levonorgestrel; GTD = gestodene: DG = desogestrel. Unless indicated otherwise, all changes are statistically significant relative to baseline levels or versus control group, as stated by investigators.

*Borderline statistical significance.

norgestrel, desogestrel, or gestodene. Desogestrel, a 3-deoxo-11-methylene derivative of levonorgestrel, has roughly the same progestogenic and androgenic potency as levonorgestrel when used alone, but it has less antiestrogenic action when combined with the same dose of ethinyl estradiol.[57] The lesser antiestrogenic activity may be linked to intermediate hepatic metabolism of this compound from inactive desogestrel to active 3-ketodesogestrel. One of its intermediate metabolites, 3β-hydroxydesogestrel, binds to the estrogen receptor, as do other compounds with hydroxy groups at C-3 and C-17,[58] and might account for some of the estrogenic activity of this compound. With regard to gestodene, a Δ15-levonorgestrel derivative, its stronger inhibitory effect on ovulation allows it to be used in even smaller dosages than levonorgestrel can,[59] although its endocrine-pharmacologic profile is similar to that of levonorgestrel.[60] In Table II, the effects on lipid levels of the high-dose combination ethinyl estradiol 50 plus levonorgestrel 250 have also been indicated for the purpose of comparison with lower-dose products.

It must be stressed that data on ethinyl estradiol plus norethisterone combinations are still rather scarce, particularly for lower-dose formulations. Also, the duration of these studies is sometimes very short (for example, 7 weeks of treatment with ethinyl estradiol 35 plus norethisterone 400 in the study of Krauss et al.[13]). The consensus emerging from most studies is that reducing the estrogen and norethisterone content in OCs helps minimize increases in total C and triglyceride levels; even more interesting is the absence of any decrease in HDL-C concentration with low-dose compounds and the trend toward increased HDL-C levels with the lowest-dose combination, ethinyl estradiol plus norethisterone 400. This increase, which is probably related to a favorable ethinyl estradiol:norethisterone ratio, applies to the HDL_3-C and probably HDL_2-C subfractions as well.[43] At the same time, increases in LDL-C that were prominent with the OCs containing up to a mean daily dose of norethisterone 750 μg (in the triphasic ethinyl estradiol plus norethisterone formulation[40]) are no longer observable with the very low-dose preparations.[41, 43] Accordingly, the epidemiologically important ratios of HDL-C:total C and HDL-C:LDL-C do not change significantly with products containing <1000 μg of norethisterone per day, provided this progestogen is combined with at least 35 μg of ethinyl estradiol daily. Studies of apolipoproteins seem to indicate an increase in both apolipoprotein A_1 and apolipoprotein B with the low-dose combinations, but there are still too few data to allow any comment.

Much more information is available concerning the preparations containing gonane derivatives and ethinyl estradiol (Table II). Here again, the high-dose combination ethinyl estradiol 50 plus levonorgestrel 250 clearly induces changes in the lipoprotein profile that closely resemble those induced by ethinyl estradiol 50 plus norethisterone 2500. The well-known preparation ethinyl estradiol 30 plus levonorgestrel 150, which was probably the earliest available lower-dose combination (about 1974), has been extensively studied, and most references can be found in Fotherby's review.[1] Compared with the high-dose preparation, this OC does not increase total C and has no effect on or only slightly increases triglyceride levels. With ethinyl estradiol 30 plus norgestrel 300, the LDL-C decrease (−24% with the high-dose product) is no longer observed or is only borderline, and the 20% decrease in HDL-C levels seen with the high-dose OC is now only about −10% from baseline, probably because of a simultaneous moderate decrease in HDL_2-C.[43] Apolipoprotein B levels are still somewhat increased. Consequently the ratios HDL-C:total C, HDL-C:LDL-C, and apolipoprotein A_1:apolipoprotein B are only slightly decreased, indicating, at least theoretically, a reduction in the atherogenic risk when compared with higher-dose progestogen-dominant OCs. This trend toward lesser OC-induced changes in lipid profile is further exem-

plified by studies of a triphasic combination containing mean daily doses of ethinyl estradiol 32 plus levonorgestrel 92. No changes in lipid and lipoprotein concentrations are observed,[52] except for a slight increase in HDL_3-C, although this rise is not reflected in a concomitant increase in HDL-C[48]; apolipoprotein A_1 and B levels are both slightly increased but not enough to provoke changes in the apolipoprotein A_1 : apolipoprotein B ratio.[38, 45, 48, 50-52, 61-63] A further decrease in the progestogen dose has been achieved in a new triphasic OC containing a mean daily dose of ethinyl estradiol 32 μg plus gestodene 79 μg, which is a slightly more estrogenic combination than the ethinyl estradiol plus levonorgestrel triphasic. In an ongoing 12-month prospective study of this new triphasic, Gaspard et al.[49] have observed only marginal changes in lipid and lipoprotein concentrations, with slight increases in total triglycerides and apolipoprotein B levels.

The monophasic combination of ethinyl estradiol 30 plus desogestrel 150 has also been widely studied, and there is a consensus (review in reference 1) that this formulation is more estrogen-dominant than is the combination containing ethinyl estradiol 30 plus levonorgestrel 150, the triphasic ethinyl estradiol plus levonorgestrel, and the triphasic ethinyl estradiol plus gestodene. It probably also is more estrogenic than all low-dose preparations containing ethinyl estradiol plus norethisterone. Consequently, about half of the studies concerning this OC report moderately increased total triglyceride levels; they also show unchanged or slightly increased HDL-C levels (about +5% to +10% from baseline), which are mainly accounted for by an increase in HDL_3-C[48] but probably also by a slight increase in HDL_2-C. Apolipoprotein A_1 levels increase and apolipoprotein B levels decrease slightly during intake of this OC.[52] The epidemiologically relevant lipoprotein and lipid ratios either do not change or increase slightly in, at least theoretically, an antiatherogenic direction. In our opinion, some concern should be raised, however, concerning the slightly excessive estrogen-dominant balance of this preparation. A consensus is emerging that for all the combination OCs reviewed, reducing the doses of both the 19-nortestosterone–derived progestogen component and the estrogen component leads to lesser changes in all measured parameters of the lipid profile. The concentrations of LDL-C are clearly proportionally higher in women treated with OCs that either contain the highest doses of progestogen or have the lowest estrogen : progestogen ratio. Triglyceride levels increase more readily with OCs containing higher amounts of estrogens or containing less antiestrogenic and/or very low-dose progestogens. HDL-C concentrations increase with higher doses of estrogens or with lower doses of progestogens and do not change with the more balanced preparations.[44] Review of the studies of low-dose OC use show that, although many lipid fraction changes are observed after 3 months of treatment, this is not a general rule, probably because changes in apoproteins proceed at a slower rate. More relevant information on lipid profiles during OC use comes from studies of 6 to 12 months' duration.[1, 11, 12] In contrast to previous assertions,[16, 18] reduction of the dose of *all* progestogens (even the more active ones, such as levonorgestrel or desogestrel, or the most antiestrogenic, such as levonorgestrel), provided that the estrogen : progestogen ratio is well adapted, helps minimize the repercussions on lipoprotein metabolism. This was well demonstrated by Larsson-Cohn et al.[38] in 1981 and again by further studies coming from different centers.[45, 52]

Carbohydrate metabolism

Carbohydrate metabolism and vascular disease. Since the first report of Waine et al.[64] in 1963 indicating a possible adverse effect of OC use on carbohydrate metabolism, many studies have investigated the extent of the potential alterations caused by different steroid types and dosages in both combination and progestogen-only OCs.

Diabetes mellitus is a well-documented independent risk factor for ischemic heart disease and cardiovascular death[65]; this risk is also partly mediated by the associ-

ation of diabetes with hyperlipidemia and hypertension and may be greater in diabetic women than in diabetic men. Moreover, impairment of glucose tolerance[66] and hyperinsulinism[67] may be associated with an increased risk of arterial disease. The plasma insulin response to a glucose load may be a sensitive indicator of the risk of arterial disease.[68] Since such abnormalities of glucose metabolism may be observed in OC users, particularly if additional risk factors such as obesity, family history of diabetes, age, and antecedents of gestational diabetes are present, it is essential to evaluate how risk may be minimized in OC users by proper drug and patient selection.[69]

Effects of sex steroids on carbohydrate metabolism. Some studies seemed to show an impairment of glucose tolerance during the luteal phase of the menstrual cycle—and hence partly in relation to progesterone secretion (review in reference 70). However, it is now well established, by means of sophisticated techniques, such as the euglycemic hyperinsulinemic glucose clamp, that glucose tolerance and insulin sensitivity are identical in both the follicular and the luteal phases of the cycle.[71]

Estrogens alone do not worsen diabetes and may even improve hyperglycemia in non–insulin-dependent diabetes.[70] Administration of synthetic estrogens, even in high doses up to 500 μg/day, does not consistently affect glucose tolerance or insulin response to a glucose load in healthy young women.[72] With synthetic estrogens contained in OCs, and particularly with higher doses (50 to 150 μg/day), a fall in the fasting plasma glucose level, a decrease in glucose tolerance mainly during the first hour after a glucose load, and a reduction of the early insulin response with subsequent enhanced insulin secretion have been repeatedly described.[73] These effects have been attributed to a direct action of estrogens on the liver and A and B cells of pancreatic islets, resulting in an overall decreased portal secretion of insulin and glucagon with an increased insulin:glucagon ratio. Impaired gluconeogenesis, reduced glycogenolysis, and increased liver glycogen storage may ensue,[74] explaining the fall in the fasting blood glucose level observed in OC users.

High doses of intramuscular progesterone (300 to 400 mg/day) equivalent to endogenous progesterone secretion during the last trimester of pregnancy, rapidly induce a decrease in glucose tolerance.[75] Tolbutamide tests performed concurrently in progesterone-treated subjects provoke an enhanced insulin response with subsequent blunted hypoglycemia.[73] These progesterone-induced changes in carbohydrate metabolism are typical of insulin resistance. Additionally, animal studies clearly show a direct effect of progesterone and progestogens on insulin release from pancreatic islets.[76]

Synthetic progestogens, administered alone even in small amounts and by the oral route, have the same potential as progesterone for impairing glucose tolerance in spite of hyperinsulinism. This has been well demonstrated in a series of studies by Spellacy et al.[77] in women receiving for 12 or more months low doses of either a 17-acetoxyprogesterone—derived progestogen (megestrol acetate, 0.5 mg/day) or one of the 19-nortestosterone–derived progestogens norethisterone (0.35 mg/day), ethynodiol diacetate (0.25 mg/day), or norgestrel (0.075 mg/day).[78-80] It is, however, obvious from these studies and from others that progestogens derived from 17-hydroxyprogesterone have a lower potential for impairing glucose tolerance and increasing insulin resistance than do the more potent 19-nortestosterone derivatives.

The mechanism of insulin resistance resulting from use of either combination or progestogen-only OCs is still poorly understood. Recent observations of Seed et al.[81] relate at least part of this resistance to potentially reduced levels of hepatic insulin receptors, resulting in decreased hepatic uptake of insulin; however, no direct evidence is currently available. A decrease in the number and affinity of peripheral insulin receptors, such as monocyte or erythrocyte receptors, has been postulated in subjects receiving progesterone, testosterone, or derived steroids in order to explain decreased insulin sensitivity.[82] However, convincing results in this field are still lacking, and our group has been repeatedly unable to observe any change in erythrocyte insulin receptor level and affinity in women receiving monophasic or sequential OCs containing ethinyl estradiol and desogestrel and triphasic OCs containing ethinyl estradiol and levonorgestrel or gestodene for 6 to 12 months.[15,49] Indeed, significant postreceptor changes in intracellular glucose metabolism may potentially contribute to insulin resistance in OC users.

Effects of high-dose OCs on carbohydrate metabolism. The numerous studies devoted to this subject have used different methods in very different populations, and the results frequently appear conflicting. From a review by Kalkhoff[70] in 1975, it appeared, however, that the different effects of combinations of estrogens and progestogens on glucose tolerance and insulin resistance are directly related not only to the respective amounts of these steroids but also to the type of progestogen used. Other important contributors to potential deterioration of glucose tolerance in OC users were preexisting abnormalities of glucose tolerance, such as impaired glucose tolerance or diabetes mellitus, age, obesity, and a familial history of diabetes or previous gestational diabetes. In a large prospective study, Phillips and Duffy[83] found that OC users had significantly lower fasting blood glucose levels and higher (by 11 mg/dl) 1-hour serum glucose levels than those of age-matched nonusers. However, past users, regardless

*Borderline statistical significance.

of the duration of use, experienced the same glucose response as that of women who had never used OCs.

There is a consensus that glucose tolerance is more impaired with overly estrogenic high-dose OCs. There is also agreement that standard dose OCs (containing 50 μg of ethinyl estradiol per day) in combination with a pregnane progestogen, such as chlormadinone acetate or megestrol acetate, cause significantly less impairment of glucose tolerance than do combinations containing high doses of estrane or gonane progestogens.[70-73] Perlman et al.[84] reanalyzed glucose tolerance data from the large prospective Walnut Creek Contraceptive Drug Study by multiple linear regression analyses in order to define relationships between specific progestogen and estrogen types and dosages and parameters of glucose tolerance. As expected, the mean 1-hour and 2-hour glucose values after an oral glucose load were higher in OC users than in nonusers and impaired glucose tolerance was observed twice as frequently in users as in nonusers. Regression slopes for the three structurally similar estrane progestogens norethisterone, norethisterone acetate, and ethynodiol diacetate indicated a 5 to 10 mg/dl increase in serum glucose per milligram of progestogen exposure, for both 1-hour and 2-hour test results, and the slopes reflected an 18 to 35 mg/dl increase per milligram of norgestrel. This correlates very well with the higher activity of this progestogen, which was discussed earlier,[37] and indicates the need to use low doses of levonorgestrel in combination OCs containing this steroid.

However, as recently observed by Vexiau et al.[85] in eight women presenting with impaired glucose tolerance, 12 months of use of ethinyl estradiol 50 μg plus norgestrel 500 μg results not only in insulin resistance but also in unexpected and paradoxical correction of glucose intolerance probably as a result of the OC-induced hyperinsulinism. Nevertheless, use of high-dose OCs in women with previous gestational diabetes or with impaired glucose tolerance usually results in rapid deterioration of glucose tolerance in more than half of the subjects. This deterioration progressed to diabetes mellitus in 44% of the patients in Kalkhoff's review,[70] probably because of the inability of the pancreas to further secrete insulin in response to the diabetogenic stress induced by the pill. In contrast, large prospective studies of women using OCs, even in high doses, have not been able to delineate a significantly increased risk of developing diabetes mellitus when these women are compared with nonusers.[86] Moreover, in a large prospective follow-up study (over a mean of 8.5 years) of women with glucose intolerance, high-dose OC use did not induce permanent changes in glucose status, although increased glucose intolerance was observed in women who were older, were obese, or had a positive family history of diabetes.[13]

Effects of low-dose OCs on carbohydrate metabolism. Most of the prospective studies of low-dose combination OCs are summarized in Table III (references 15, 17, 35, 50, 61, 62, 87-91). Changes in blood glucose and insulin levels, although statistically significant, are usually within the normal range, and most of the fluctuations reported do not appear to be clinically signif-

icant. This is particularly the case for combination OCs containing low doses (less than 1 mg a day) of estrane progestogens, which seem to induce fewer changes in carbohydrate metabolism than do the corresponding progestogen-only minipills.[78-80] In the study of Rabe et al.,[87] the triphasic preparation containing mean daily doses of ethinyl estradiol 35 plus norethisterone 750 μg caused a transient increase in 1-hour and 2-hour glucose values and in plasma insulin levels when compared with basal pretreatment levels. At 12 months, however, the differences in glucose tolerance and insulin response were no longer statistically significant. No change in carbohydrate metabolism was apparently observed with low-dose combination OCs containing either 500 μg or 400 μg of norethisterone.[88,89]

The effects of carbohydrate metabolism of the combination preparation containing the intermediate dose of levonorgestrel 150 μg/day are controversial. Ahren et al.[90] did not observe any adverse effect with this OC, in contrast to the findings reported in the World Health Organization multicenter study[35] and in Wynn's study.[17] Wynn observed a deterioration of glucose tolerance that increased with time for up to 36 months of study. An accompanying increase in insulin response developed during OC use, but it could not prevent an increase in the ratio of incremental glucose area : incremental insulin area. Impaired glucose tolerance developed in six subjects. However, the major drawback of this study is an uncommonly high dropout rate: 210 women began the study, but only 17 remained under investigation after 3 years. Consequently, these results must be regarded as circumstantial and, in our opinion, no firm conclusion can be drawn from this study. In a preliminary study of a combination monophasic OC containing a similar dose of desogestrel (150 μg a day), Schijf et al.[62] reported statistically significant increases in blood glucose and plasma insulin levels after 6 months of treatment. However no pathologic values were recorded.

The same observation was also reported in a study of a triphasic OC containing a low mean daily dose of levonorgestrel.[50] However, these data are not confirmed by a careful 12-month prospective study,[91] in which we compared the treated subjects at 0, 6, and 12 months of use with a group of matched nonusers. No change in glucose tolerance was recorded in any individual during treatment, and a slight increase in insulin response was only transiently observed in the sixth month of study. Additionally, no changes in insulin erythrocyte receptor number or affinity were recorded. These results are at variance with a previous 6-month study,[15] in which we observed a slight decrease in glucose tolerance associated with a decrease in insulin response when compared with pretreatment levels. This difference could be attributed to circannual changes in glucose-insulin homeostasis, as previously observed by Reinberg et al.[14] The protocol of our subsequent study was accordingly modified to avoid this physiologic interference. Skouby et al.[61] in a recent study did not observe any effect of the levonorgestrel-containing triphasic on carbohydrate metabolism. In a new triphasic OC containing a minimal mean daily dose of 79 μg of gestodene, the balance is slightly more estrogen dominant than in the triphasic containing levonorgestrel. In women using this OC, a slight but significant decrease in glucose tolerance is observed at 6 months, with a subsequent full recovery at 12 months. On the other hand, no change in insulin response when compared with the baseline value was recorded throughout the 12 months of study (Gaspard UJ, Lepot MR, Jaminet C, Jandrain B, Lefebvre PJ. Carbohydrate metabolism in women receiving two low-dose triphasic oral contraceptives for one year. Unpublished data.)

Thus decreasing the gonane progestogen dose in OCs is associated with reduced effects on carbohydrate metabolism. With the triphasic formulations, changes in glucose tolerance are virtually nonexistent. With the gestodene-containing triphasic, induced insulin resistance, which seems to be the most sensitive effect of progestogens on carbohydrate metabolism, is completely absent. In addition, it is noteworthy that in women with previous gestational diabetes who received the levonorgestrel triphasic for 6 months, the glucose, insulin, and the glucagon responses to oral glucose remain unchanged during the whole treatment period.[61]

Comment

Analysis of epidemiologic data concerning the association of cardiovascular disease with OC use suggests that OC use is probably not an independent risk factor but that it can amplify the deleterious effects of other direct risk factors. Risk factors for atherosclerosis that may be directly influenced by OC intake are altered lipoprotein metabolism (eventually resulting in decreased HDL-C, HDL_2-C, and apolipoprotein A_1 concentrations and/or in increased LDL-C, total C, apolipoprotein B, and triglyceride levels) and altered carbohydrate metabolism (characterized by impaired glucose tolerance and hyperinsulinism caused by insulin resistance). In fact, adverse effects on these metabolic parameters have been repeatedly described with the use of high-dose, progestogen-dominant OCs. Their formulations accordingly have been carefully adapted in a search for OCs with the least possible effects on diverse metabolic end points. Data emerging from new and ongoing prospective studies show definitely less impact of new OC formulations on metabolism. Low-dose combination OCs containing a daily dose of ≤35 μg of ethinyl estradiol in association with a minimal amount of estrane or gonane 19-nortestosterone progestogen (equivalent to ≤750 μg of norethisterone and to ≤100 μg of levonorgestrel),

preferably with a slight estogen dominance, seem best devised for respecting metabolic neutrality. The assumption that levonorgestrel derivatives are "too potent" is refuted by the observation of favorable metabolic results obtained with OCs containing very low doses of these progestogens, which compare equally well with results obtained with ethinyl estradiol/estrane preparations.

However, because of the appreciable metabolic changes that can occur with only slight alterations of OC formulation, careful evaluation of the metabolic effects of each new OC preparation is mandatory. The best approach to assessing effects on lipoprotein metabolism involves not only recording changes in levels of lipoproteins or even their subfractions but also analyzing apoprotein and lipid content and composition for each lipoprotein. Indeed, OC-induced changes in lipoproteins,[91] which are not reflected in a simple lipid or lipoprotein level analysis, can greatly alter lipid metabolism. In addition, before these low-dose formulations truly can be considered neutral, it will be necessary to gather more data on alteration of fatty acid composition, on key enzymes of lipid metabolism (for example, lecithin-C acetyl transferase, hepatic lipase), and on lipid and lipoprotein synthesis and metabolic rate during OC use.

With respect to carbohydrate metabolism, a better appreciation of insulin resistance is necessary, as are continued studies of its mechanism of appearance and development during OC use. Determination of C-peptide levels, in addition to insulin concentrations, appreciation of insulin receptor levels, and the use of glucose clamp–related techniques may potentially help to quantify more accurately the metabolic burden imposed by OCs, even in low dosages. Finally, it must be stressed that beyond their effects on carbohydrate and lipid metabolism, OCs display many other actions. These actions may have even more important implications with respect to cardiovascular disease and certainly deserve in-depth continuing study.

I wish to thank M. Lepot, M.D., D. Gillain, M.Sc., and R. Lambotte, M.D., Ph.D., Department of Obstetrics and Gynecology, and P. Lefebvre, M.D., Ph.D., and J. Sulon, Ph.D., Institute of Medicine, University of Liège, for their scientific collaboration in the preparation of this manuscript.

Coagulation effects of oral contraception

John Bonnar, M.D.
Dublin, Ireland

In Europe and North America, estrogen/progestogen oral contraception has been associated with an increase in venous thromboembolism, myocardial infarction, and stroke. These hazards are found mainly in smokers and in women over the age of 35. Venous thromboembolism appears to correlate with the estrogen dosage, and the arterial complications with both the estrogen and progestogen components. Blood coagulation and vascular thrombosis are intimately related. Estrogen/progestogen oral contraception affects blood clotting by increasing plasma fibrinogen and the activity of coagulation factors, especially factors VII and X; antithrombin III, the inhibitor of coagulation, is usually decreased. Platelet activity is also enhanced with acceleration of aggregation. These changes create a state of hypercoagulability that, to a large extent, appears to be counterbalanced by increased fibrinolytic activity. Studies of the oral contraceptives in current use show that the coagulation effects depend on the dosage of estrogen and the type of progestogen used in combination. Current research is aimed at finding the estrogen/progestogen formulations that induce the least changes in the coagulation system and other physiologic processes. In this respect, the new low-dose formulations are a major step forward and should reduce the risk of vascular thrombotic complications. (Am J Obstet Gynecol 1987;157:1042-8.)

Key words: Estrogen/progestogen contraceptives, thromboembolism, myocardial infarction, stroke, dosage of estrogen, type of progestogen

After 25 years of extensive use of oral contraceptives (OCs), the most important concern about the effects of these substances on women's health is the increased risk of cardiovascular disease, specifically, venous thromboembolic disease, myocardial infarction, and stroke.[1,2] These hazards increase especially in older patients and with smoking. The information on the vascular effects of OCs is derived almost entirely from the epidemiologic research carried out in Europe and in the United States and is based on preparations that contain one of several progestogens in combination with 50 μg of mestranol or ethinyl estradiol. These findings therefore relate to countries in which the incidence of cardiovascular disease is high; thus they may not be relevant to countries in which the incidence of these diseases is low. In this context, it should also be noted that important differences in coagulation and hemostatic tests have been shown in healthy women from different ethnic groups and geographic locations,[3] and that epidemiologic studies from certain countries do not demonstrate an increased incidence of vascular disease in association with oral contraception.[4]

Since 1974, important information on the effects of OCs on morbidity and mortality has come from three cohort studies that involved more than 80,000 women, half of whom were using OCs (The Royal College of General Practitioners Oral Contraception Study, the Oxford/F.P.A. Contraceptive Study, and the Walnut Creek Contraceptive Drug Study[2]). The Royal College of General Practitioners data suggest that the morbidity from vascular complications was increased fourfold; most deaths were caused by ischemic heart disease or subarachnoid hemorrhage and were concentrated in women over the age of 35 or older and in smokers (Table I). In general, among women of reproductive age the risk of death from a vascular complication attributable to OCs was 22 to 24 deaths per 100,000 women per year in both current and past users.

The effect of oral contraception on the incidence of venous thromboembolic disease is shown in Table II. Oral contraceptive use was considered to be responsible for 19 cases of overt venous thromboembolic disease per 10,000 current users per year; just over half of these cases were superficial leg vein thrombosis. The relative risk of idiopathic deep vein thrombosis and pulmonary embolism was approximately fourfold, and the relative risk of postoperative venous thrombosis was twofold.

Pathogenesis of vascular complications

The pathogenesis of venous thromboembolism in OC users may relate to increases of blood coagulability (including changes in the levels of coagulation factors and inhibitors and altered fibrinolytic and platelet activity) and to changes in the structure of veins and arteries (such as endothelial proliferation and changes in the

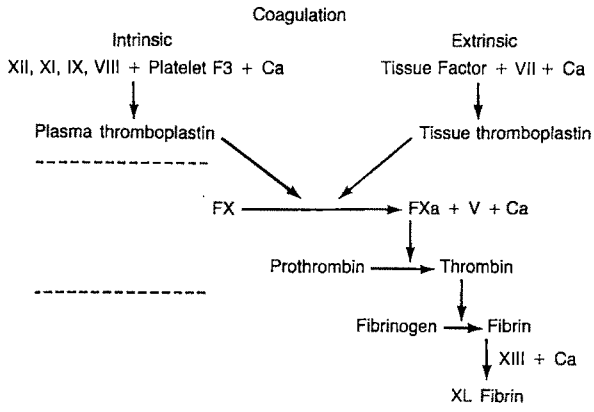

Fig. 2. Intrinsic and extrinsic coagulation pathways.

Table I. Royal College of General Practitioners data on mortality from vascular complications in OC users

Deaths			*Relative risk*		*Attributable risk*	
Current user	*Past user*	*Never user*	*Current versus never*	*Past versus never*	*Current versus never*	*Past versus never*
29	31	7	4	4	22	24

Number of deaths and attributable risk are per 100,000 per year.

Table II. Venous thromboembolic disease

Type	*Incidence (cases/10,000 women/yr)*		*Relative risk*	*Attributable risk (cases/10,000 women/yr)*
	Current users	*Nonusers*		
Superficial leg vein thrombosis	19	8	2	11
Deep vein thrombosis or pulmonary embolism	11	3	4	8
Postoperative venous thrombosis	61	30	2	31

rate of venous flow). The risk of overt venous thromboembolism appears to be related primarily to the estrogen component of OCs and is confined to the time of current usage.

The pathogenesis of arterial vascular complications—myocardial infarction and stroke—associated with OC use appears to be much more complex than that responsible for venous complications and relates to both increased platelet activity and fibrin deposition and to other factors that contribute to accelerated atherogenesis. These factors include increased arterial blood pressure and changes in glucose tolerance and lipoprotein and cholesterol metabolism. Once an atherogenic lesion develops, the process is difficult to reverse because of built-in self-maintaining or autoregulating mechanisms that are involved in this arterial lesion. The progestogen component, which was formerly regarded as the "innocent" party of the combined OC, is now considered to be an important factor with respect to arterial vascular disorders.

Blood coagulation and thrombosis

Blood coagulation and thrombosis are not identical processes, but they are intimately related. Vascular thrombosis can be regarded as hemostasis involving platelets and blood clotting occurring in the wrong place and involving an intact blood vessel. When new types of OCs or estrogen-containing drugs are introduced, it is important to investigate their effects on the physiologic processes involved in hemostasis.

The blood coagulation and fibrinolytic systems are normally in a dynamic equilibrium that controls the formation and removal of fibrin. Both systems are dependent on proteolytic enzymes, which are produced from inactive precursors: With blood coagulation, thrombin is derived from prothrombin, and in the fi-

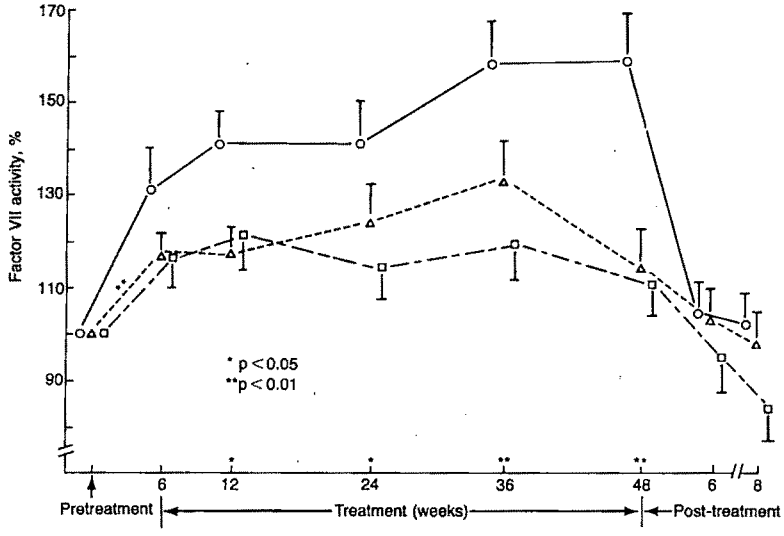

Fig. 3. Effects of oral contraceptives containing 50 and 30 μg estrogen on coagulation factor VII. Norethindrone acetate plus 50 μg estrogen, o——o; norethindrone acetate plus 30 μg estrogen, Δ - - - - Δ; levonorgestrel plus 30 μg estrogen, □ — — — □.

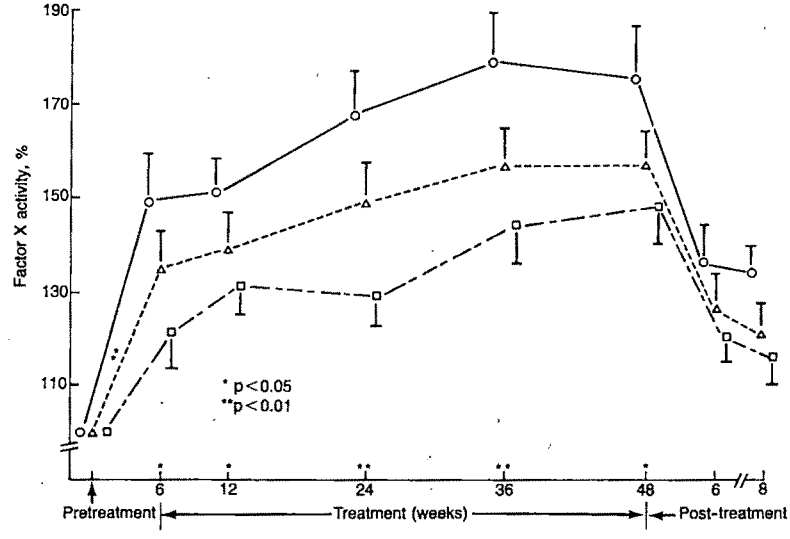

Fig. 4. Effect of oral contraceptives containing 50 and 30 μg estrogen on coagulation factor X. Norethindrone acetate plus 50 μg estrogen, o——o; norethindrone acetate plus 30 μg estrogen, Δ - - - - Δ; levonorgestrel plus 30 μg estrogen, □ — — — □.

Table III. Effect of 50 and 30 μg estrogen OCs on the hemostatic system

Formulation	*No. of patients*
Norethindrone acetate: 1.0 mg norethindrone acetate and 50 μg mestranol	31
Norethindrone acetate: 1.5 mg norethindrone acetate and 30 μg ethinyl estradiol	27
Levonorgestrel: 150 μg levonorgestrel and 30 μg ethinyl estradiol	28

brinolytic system plasmin is derived from plasminogen (Fig. 1).

Blood coagulation and fibrinolysis also share a common activation from factor XII. The coagulation system is designed as a biochemical amplifier, and the initial trigger may emanate from within the blood itself (the intrinsic system) or from outside the blood vessel from the tissues (the extrinsic system). The interaction of coagulation factors leads to the formation of either plasma thromboplastin or tissue thromboplastin, which

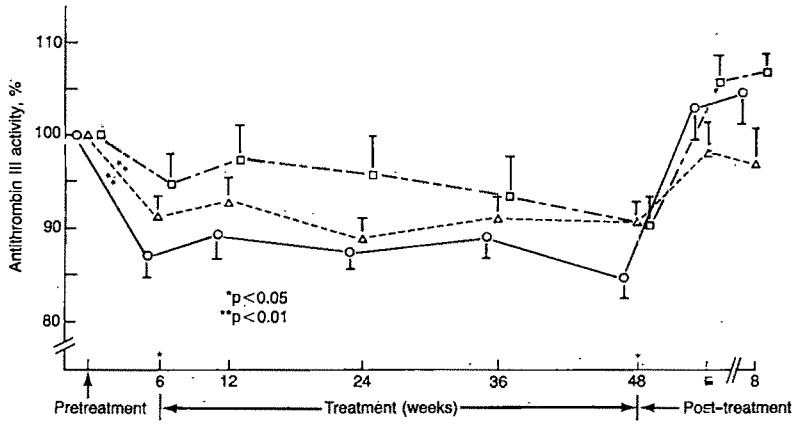

Fig. 5. Effect of oral contraceptives containing 50 and 30 μg estrogen on antithrombin III. Norethindrone acetate plus 50 μg estrogen, o——o; norethindrone acetate plus 30 μg estrogen, Δ - - - - Δ; levonorgestrel plus 30 μg estrogen, □ — — — □.

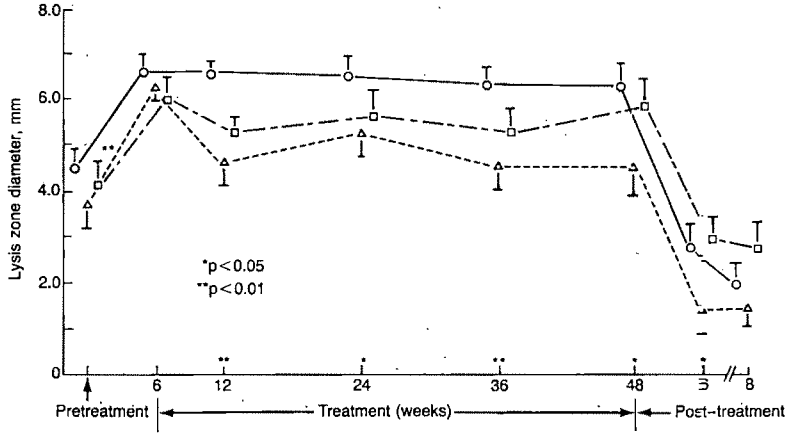

Fig. 6. Effect of oral contraceptives containing 50 and 30 μg estrogen on the fibrinolytic system (fibrin plate assay [resting]). Norethindrone acetate plus 50 μg estrogen, o——o; norethindrone acetate plus 30 μg estrogen, Δ - - - - Δ; levonorgestrel plus 30 μg estrogen, □ — — — □.

converts factor X to its activated form. The complex of activated factor X, with factor V and calcium converts prothrombin to thrombin. Thrombin converts soluble fibrinogen into fibrin, which in the presence of factor XIII and calcium forms cross-linked fibrin (Fig. 2).

Estrogen therapy is known to influence the clotting mechanism by increasing the levels of factors II, VII, VIII, IX, and X, fibrinogen, and soluble fibrin. Estrogen also decreases the levels of antithrombin III and vessel wall fibrinolytic activator. The effects of OCs on blood coagulation have been recently reviewed by Beller and Ebert[5] and Notelovitz.[6]

Comparative studies of OCs

The comparative effects of different low-dose estrogen/progestogen contraceptives on the hemostatic system are best investigated by serial studies in healthy women. We have carried out two major studies, with the following objectives: (1) to compare the effects of 50 and 30 μg estrogen OCs on blood coagulation, fibrinolysis, and platelets; (2) to compare the effects of 30 μg ethinyl estradiol combined with different progestogens.

Comparison of 50 μg versus 30 μg estrogen. Participants in this study received either 50 μg of mestranol combined with 1.0 mg norethindrone acetate, 30 μg of ethinyl estradiol in combination with 1.5 mg of norethindrone acetate, or 30 μg of ethinyl estradiol combined with 150 μg of levonorgestrel[7] (Table III). Blood samples were taken for laboratory assay during a pretreatment cycle, after 6 12, 24, 36, and 48 weeks of treatment, and at 6 and 8 weeks after cessation of treatment.

Factor VII levels increased sharply with both estro-

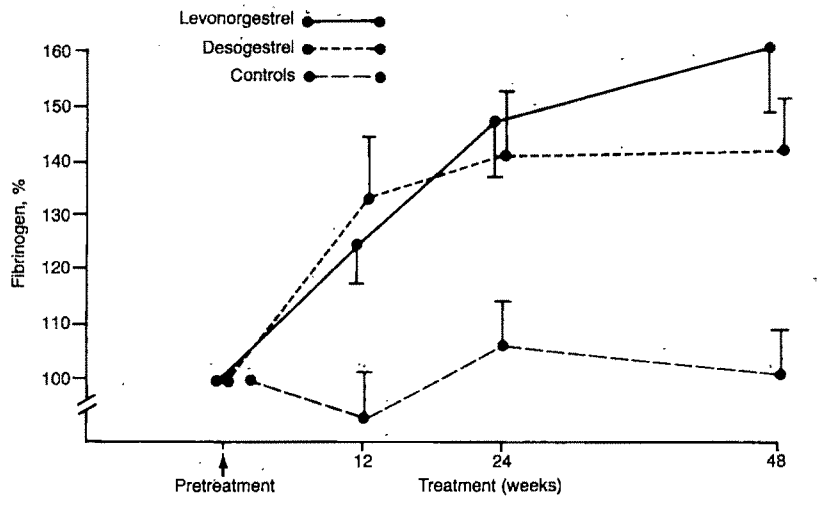

Fig. 8. Effects of levonorgestrel triphasic and desogestrel monophasic on fibrinogen.

Table IV. Comparative study of triphasic levonorgestrel and monophasic desogestrel

Formulation	*No. of patients*	*1 yr*
Levonorgestrel: 50-125 μg levonorgestrel combined with 30-40 μg ethinyl estradiol (triphasic formulation)	30	20
Desogestrel: 150 μg desogestrel and 30 μg ethinyl estradiol	36	13

gen dosages, but the increase with the 50 μg OC was significantly higher than that occurring with the two 30 μg preparations (Fig. 3). Similar results were noted with factor X. The least increase in factor X activity occurred with the levonorgestrel combination (Fig. 4). Levels of the coagulation inhibitor antithrombin III decreased significantly in patients who received 50 μg OCs and to a lesser extent with the 30 μg OCs that contained norethindrone acetate. In the group who received the 30 μg OC that contained levonorgestrel, antithrombin III levels did not significantly decrease until the forty-eighth week (Fig. 5).

The resting plasma fibrinolytic activity was significantly increased with 50 and 30 μg preparations, and the greatest increase was found with the 50 μg OC (Fig. 6). Fibrinolytic activity after venous occlusion also increased significantly with all three preparations.

Spontaneous platelet aggregation with the Chandler tube method showed that both the 50 and 30 μg formulations produced significant shortening of the ag-

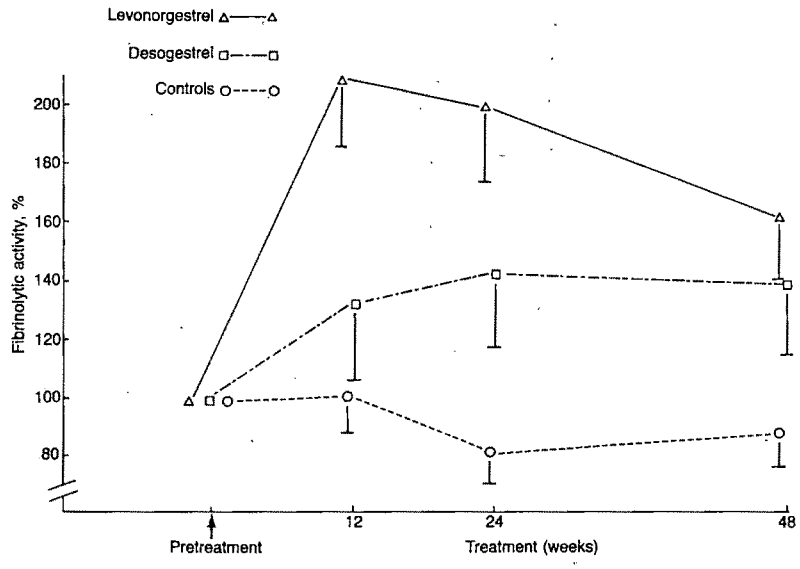

Fig. 9. Effects of levonorgestrel triphasic and desogestrel monophasic on fibrinolytic activity.

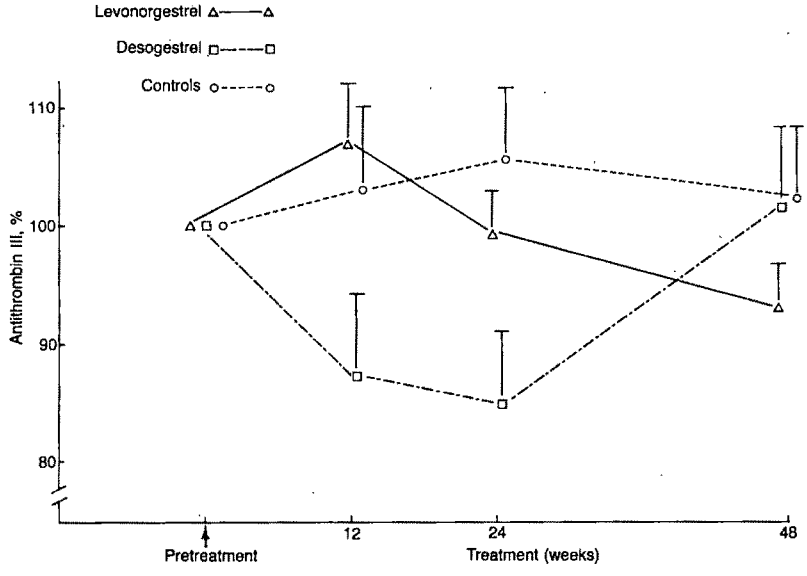

Fig. 10. Effects of levonorgestrel triphasic and desogestrel monophasic on antithrombin III (immunologic method).

gregation time, indicating enhanced platelet activity (Fig. 7).

These studies show that: (1) The effects of ethinyl estradiol on coagulation, fibrinolysis, and platelet function are related to dose, with 50 μg producing significantly greater changes than 30 μg; (2) the effects of 30 μg of ethinyl estradiol are modified by the progestogen that is used in combination.

Effects of different progestogens. Recently, we have compared the effects of triphasic levonorgestrel with monophasic desogestrel (Table IV). The effects of both combinations on fibrinogen are shown in Fig. 8. Fibrinolytic activity increased less with desogestrel than with triphasic levonorgestrel (Fig. 9). We also found that antithrombin III levels remained unchanged with triphasic levonorgestrel and decreased with desogestrel at 12 and 24 weeks on treatment but not at 48 weeks (Fig. 10).

In summary, these studies, which have compared 50 μg estrogen contraceptives with 30 μg estrogen contraceptives and different progestogens, show clearly that the changes in coagulation activity and fibrinolysis are related to the dose of estrogen and progestogen. The progestogen that is used in combination with low-

dose estrogen may potentiate or reduce the estrogen effects. The low-dose OC formulations in current use produce significantly less change in the hemostatic system than do preparations that contain 50 μg of estrogen. The estrogen/progestogen combinations also increase fibrinolytic activity, which most probably balances the increase in coagulation activity, thus preserving the dynamic equilibrium between coagulation and fibrinolysis.

Current research is aimed at finding low-dose formulations of estrogen/progestogen that will produce the least change in the hemostatic system and in other metabolic processes. This appears to be the most logical way of minimizing the risk of vascular complications and thus increasing the safety of oral contraception for the millions of women who use this method of fertility control.

I would like to thank Dr. Ali Sabra, Leisha Daly, and Eilis Carroll for their excellent teamwork in these research studies.

Progestogen potency in oral contraceptive pills

Michael D. G. Gillmer, M.D.
Headington, Oxford, United Kingdom

The most important target organs for combined oral contraceptive preparations are the anterior pituitary gland and the uterus. The long-term unopposed administration of estrogen produces endometrial hyperplasia and amenorrhea, which are unacceptable to most women and their medical advisors. Cyclic administration of progestogens in combination with the estrogen, however, produces predictable endometrial shedding and achieves a regular and acceptable bleeding pattern in most women. This was the main reason that the "delay of menses" test was adopted as the earliest clinical means of comparing the relative potencies of progestogens that were administered orally. Recently attempts have been made to compare the potency of progestogens on the other organ systems by the extrapolation of data derived from studies on the endometrium. This is inappropriate, inasmuch as the effects of progestogens and estrogens independently and in combination differ greatly depending on the target organ. In this article, the literature on this controversial subject is reviewed. (Am J Obstet Gynecol 1987;157:1048-52.)

Key words: Oral contraceptives, progestogen potency, delay of menses test, lipid metabolism

To appreciate fully the confusion that currently surrounds the concept of the potency of progestogen, it is necessary to know the early history of the combined oral contraceptive (OC).

History of the combination pill

The first 19-norprogestogen, norethisterone, was synthesized in October 1952, and the U.S. patent for the drug was filed a month later by Carl Djerassi on behalf of Syntex. In August 1953, nearly a year later, Frank B. Colton of Searle filed the patent for norethynodrel. Although it was known that norethynodrel was converted to norethisterone by weak acids and that this conversion almost certainly occurred in the stomach after ingestion, commercial reasons led to the choice of norethynodrel as the preparation that was used in the first studies of the OC pill. According to Vaughan,[1] the reason given for this decision was that norethisterone had been shown to produce testicular enlargement in rats, and it was feared that this compound might have masculinizing effects. However, Pincus, who played a

From the John Radcliffe Maternity Hospital.

major part in the early studies on the pill, was closely associated with Searle, and it is not altogether surprising that he and his associates favored the Searle compound in clinical trials. Thus even the very earliest stages in the development of the OC pill were marked by confusion about the relative actions of its progestogen components.

Further confusion followed the discovery that norethynodrel contained an estrogen contaminant, mestranol. When this contaminant was eliminated, cycle control, which had previously been satisfactory, became unpredictable and breakthrough bleeding occurred. The estrogen was therefore reintroduced in an amount that was equivalent to 1.5% of the progestogen dose. Thus it is apparent that the resulting "combination pill" Enovid, which contained 10 mg of norethynodrel and 150 μg of mestranol, was essentially a product of chance. This early experience with the pill clearly demonstrated an interaction between the estrogen and the progestogen components on the endometrium, an interaction that has frequently been ignored when progestogens such as levonorgestrel and desogestrel have been compared with the earlier products that were derived from norethisterone.

Emergence of potency as an issue

Until recently, the relative potency or bioactivity of the constituents of OCs had been of little interest to clinicians. In 1983 the publication by Pike et al.[2] of data that linked the risk of breast cancer to the progestogen content of the pill, and in particular the "potency" of the progestogens in different preparations, has, however, focused attention on this issue.

Of the innumerable target organs for the steroids in combination OC preparations, the anterior pituitary gland and the uterus are clinically the most important. The initial doses of estrogen and progestogen "chosen" for the pill appeared to inhibit ovulation effectively, but in practice it was difficult to assess "potency" by comparing the effects of different progestogens on the ovulatory process. In addition, it soon became apparent from the early clinical trials that irregular bleeding was unacceptable to women taking the pill and that this effect on the endometrium was likely to be as important a factor to the success of the pill as its ability to prevent pregnancy.

The delay of menses test

The endometrial effects of the pill were relatively easy to measure in clinical practice; therefore it was logical that the earliest efforts to compare the potency of progestogen in women relied on the so-called delay of menses test. This originated from an observation by Greenblatt et al.[3] that if women with normal menstrual cycles were given a progestogen, but not an estrogen, after they had ovulated, menstruation could be postponed. On the basis of these observations, Swyer et al.[4] developed an assay system in which they administered the test dose of progestogen for 20 days beginning on the twentieth day of the cycle. If "menstruation" was postponed to the fortieth day, the result was positive; if not, it was negative. Adjustment of the dose enabled a multipoint assay from which the median effective dose could be established to enable the comparison of the relative potencies of different progestogens.

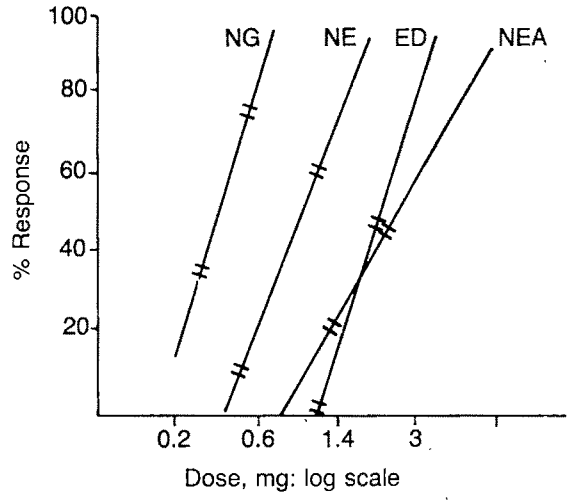

Fig. 1. Dose-response lines in the delay of menses test to show parallelism. *NG*, Norgestrel; *NE*, norethisterone; *ED*, ethynodiol diacetate; *NEA*, norethisterone acetate. Constant estrogen dose of 50 μg.

Table I. Activity of progestogens in the delay of menses test[15]

Progestogen	*Greenblatt*	*Swyer*
Norethisterone	1	1
Norethisterone acetate	2	0.4
Ethynodiol diacetate	15	<1
Norgestrel	30	2.5

The application of this test to different progestogens has given widely differing results as shown in the extensively quoted studies of Greenblatt and Swyer (Table I). These results have been criticized for several reasons.[5-7] First, the biologic activity of the various progestogens differs greatly depending on whether the women receiving them have been treated with estrogen. Second, there have been variations in the amount of estrogen that is combined with the progestogen in the study. Third, the published comparisons have seldom been based on parallel dose-response curves. Although the data published by Greenblatt[8] do not appear to be standardized, those of Swyer largely satisfy the above criticisms. The most recent studies of Swyer[9, 10] provide the only data available on the delay of menses test in

Table II. Plasma high-density lipoprotein cholesterol in women receiving combination oral contraceptive preparations that contain 30 to 35 μg of ethinyl estradiol and varying doses of levonorgestrel, norethisterone, or ethynodiol diacetate

Progestogen	*Dose (μg)*	*High-density lipoprotein cholesterol (mmol/L) (mean ± SD)*
Levonorgestrel (plus 30 μg ethinyl estradiol) (n = 20)	50-75-125	1.53 ± 0.36
	150	1.50 ± 0.19
	250	1.38 ± 0.19
Norethisterone (plus 35 μg ethinyl estradiol) (n = 20)	500	1.61 ± 0.22
	1,000	1.48 ± 0.20
Ethynodiol diacetate (plus 30 μg ethinyl estradiol) (n = 20)	2,000	1.39 ± 0.20
Controls (n = 20)	Nonpregnant	1.57 ± 0.26
	Pregnant	1.65 ± 0.35

Table III. Plasma high-density lipoprotein cholesterol in women receiving triphasic preparations containing levonorgestrel or gestodene

	High-density lipoprotein cholesterol (mmol/L) (mean ± SD)	
Progestogen	*Before therapy*	*Sixth month*
Levonorgestrel (n = 18)	1.50 ± 0.33	1.54 ± 0.34
Gestodene (n = 16)	1.50 ± 0.25	1.51 ± 0.25

women treated with combination OC preparations that contain 50 μg of ethinyl estradiol (Fig. 1). The relative potency or bioactivity of the progestogens included in this study is in keeping not only with the recent evidence that norethynodrel and ethynodiol diacetate must be converted to norethisterone to become bioactive but also with the available data on endometrial subnuclear vacuolation produced by these progestogens.[11, 12] These data would suggest that the relative bioactivity on the endometrium of norethisterone (and the progestogens derived from this compound), when combined with 50 μg of ethinyl estradiol, is one fifth that of levonorgestrel in combination with the same amount of estrogen. It is important to be aware that no comparable data exist for preparations that contain 30 to 35 μg of ethinyl estradiol or preparations that contain the newer progestogens such as desogestrel, gestodene, or norgestimate.

Effect of progestogens on lipid metabolism

Interpretation of the biologic activity of progestogens was further complicated by the recognition that no synthetic progestogen has pure progestogenic activity. The chemical origin of the 19-norprogestogens from androgens confers weak androgenic (or antiestrogenic) actions, and the conversion of norethisterone-derived compounds to estrogen may paradoxically produce estrogenic actions.[13] Whereas estrogens and progestogens act synergistically on the endometrium, their effects on certain metabolic processes are antagonistic. This is especially relevant to lipoprotein metabolism. The data of Wahl et al.[14] on the relative effects of the older high-dose pills demonstrated that these pills had an essentially estrogen-dominant effect, as judged by the significant increases in total triglycerides and the low-density lipoprotein cholesterol that they produced. On the other hand, the high-density lipoprotein cholesterol concentrations rose in women using norethisterone-derived progestogens and fell in women who received a high dose of norgestrel. These observations highlight the virtual impossibility of meaningful comparisons of progestogen potency in relation to lipoprotein metabolism unless the doses of both the estrogen and the progestogen in the OCs being studied are taken into account.

In the last decade, efforts have been made to minimize the potentially atherogenic reduction in the high-density lipoprotein cholesterol that was observed with some of the relatively progestogen-dominant pills that were used in the 1970s because of fears that these changes might account for the significant increase in cardiovascular disease mortality rates reported in epidemiologic studies of pill users.[15] Recent data collected in Oxford and elsewhere on modern low-dose combination OC preparations suggest that this aim has largely been achieved (Tables II and III).

Progestogens and the breast

Limited studies that are available on the breast suggest that whereas progestogens inhibit endometrial proliferation, natural progesterone has the opposite effect on breast lobule epithelium[16] (Fig. 2). Therefore the relative bioactivity observed in studies of proges-

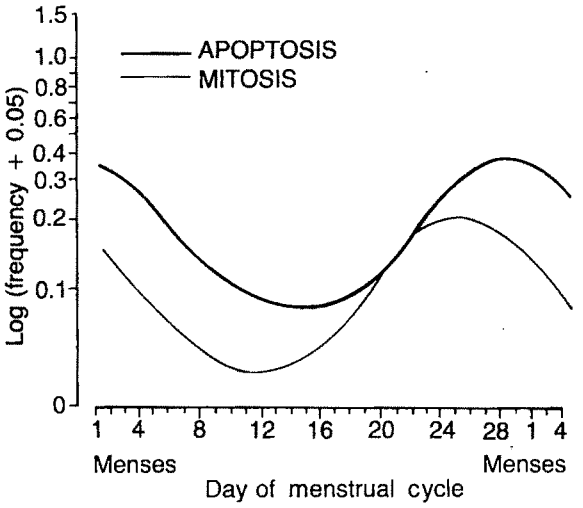

Fig. 2. Mitosis and apoptosis in the menstrual cycle.

togens on the endometrium cannot be extrapolated to the breast. Although studies are in progress to clarify the effect of the pill on this target organ (Anderson TJ, personal communication), their results are not yet available.

The future

This brief review cannot examine the many effects of OCs on end-organs, but certain general points can be made. New combinations of estrogen and progestogen must be "designed" not only to be highly effective in inhibiting ovulation and altering cervical mucus and endometrium but also in achieving optimal cycle control with minimal metabolic perturbation. This involves careful study of as many measurable end points as possible, including lipid and carbohydrate metabolism and coagulation processes. It will never be possible to assess all effects on end-organs and some chances will have to be taken, as they were with Enovid.

Several questions remain to be answered. For example, do the increases in high-density lipoprotein cholesterol (in particular the high-density lipoprotein 2 subfraction) that have been observed with recent formulations protect the patient from atherogenic disease? Does it matter that most of these preparations continue to produce significant alterations in coagulation factors[17] and other proteins such as sex hormone–binding globulin?[18] Do minor alterations in metabolic processes matter if values remain within the normal range? Are the biologic effects of OCs related to the highly variable circulating concentrations of the individual components that have been observed[7,19-21] (Figs. 3 and 4), and, if so, should efforts be made to tailor the "pill dose" to the needs of each person? This would presumably mean that it would be more appropriate for those

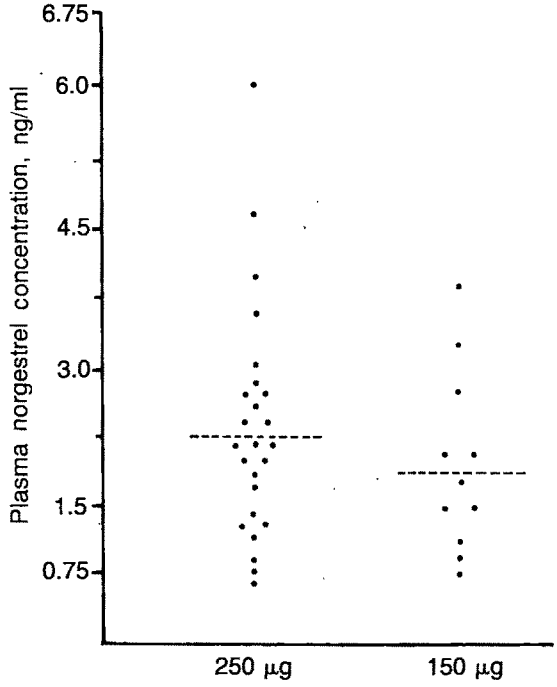

Fig. 3. Plasma norgestrel concentrations in women receiving long-term treatment with combined OCs containing 30 μg of ethinyl estradiol and either 150 or 250 μg of levonorgestrel. (Samples taken 12 hours after ingestion.)

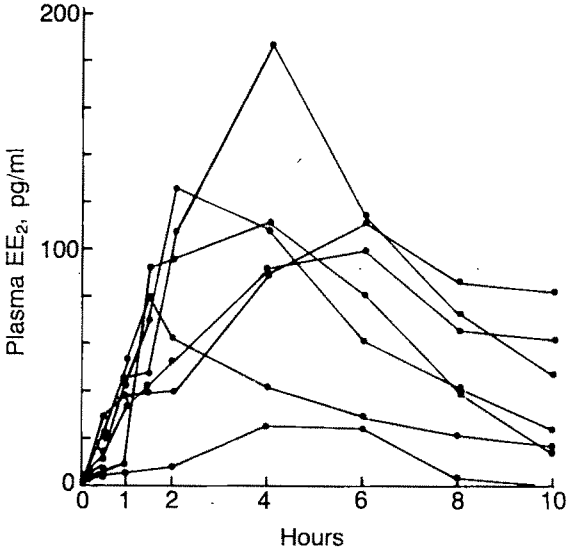

Fig. 4. Individual variation in plasma levels of ethinyl estradiol *(EE_2)* given under rigidly standardized conditions.

women who experience poor cycle control while taking low-dose preparations to take the older high-dose preparations. It will take many years to answer these questions and until then we will have to accept our very incomplete understanding of "progestogen potency" and the pill.

Phasic approach to oral contraceptives

Ralph W. Hale, M.D.

Honolulu, Hawaii

Oral contraceptives were initially very high in estrogen and progestogen and had a uniform dosage schedule throughout the entire cycle. These early oral contraceptives were associated with high rates of side effects and complications. As a result, the hormone levels have been gradually reduced to attain the minimal amount necessary for contraception while most of the undesired side effects and complications have been eliminated. Recently, a new approach has been added. This mechanism consists of altering the dose of estrogen or progestogen or both during the month and is referred to as the phasic approach. The newest phasic pills now use a triphasic approach. Three basic formulations of the triphasic pill have been developed. In two of the three formulations, the progestogen level is altered, whereas the estrogen level remains stable; in the third formulation, both estrogen and progestogen are changed. Multiple clinical studies of the triphasics, such as ethinyl estradiol and levonorgestrel, prove that there is a significant reduction in the incidence of side effects and complications related to oral contraception. (Am J Obstet Gynecol 1987;157:1052-8.)

Key words: Oral contraceptives, triphasics, reduction of side effects

Ovulation is a complex interaction of multiple neuroendocrine and hormonal events (Fig. 1).[1] Interruption of this relationship results in anovulation and infertility.[2] If the interruption is voluntary, its mechanism should be as free as possible from undesirable side effects and complications.

From the Department of Obstetrics and Gynecology, John A. Burns School of Medicine, Kapiolani-Children's Medical Center.

In the early and mid-1950s, researchers developed steroidal medications that were effective in interrupting these ovulation pathways and producing a state of anovulation and temporary infertility. These medications were first marketed in the early 1960s and used a 19-nortestosterone compound with a synthetic estrogen. The original formulation contained 9.85 mg of norethynodrel acetate and 0.150 mg of mestranol. How-

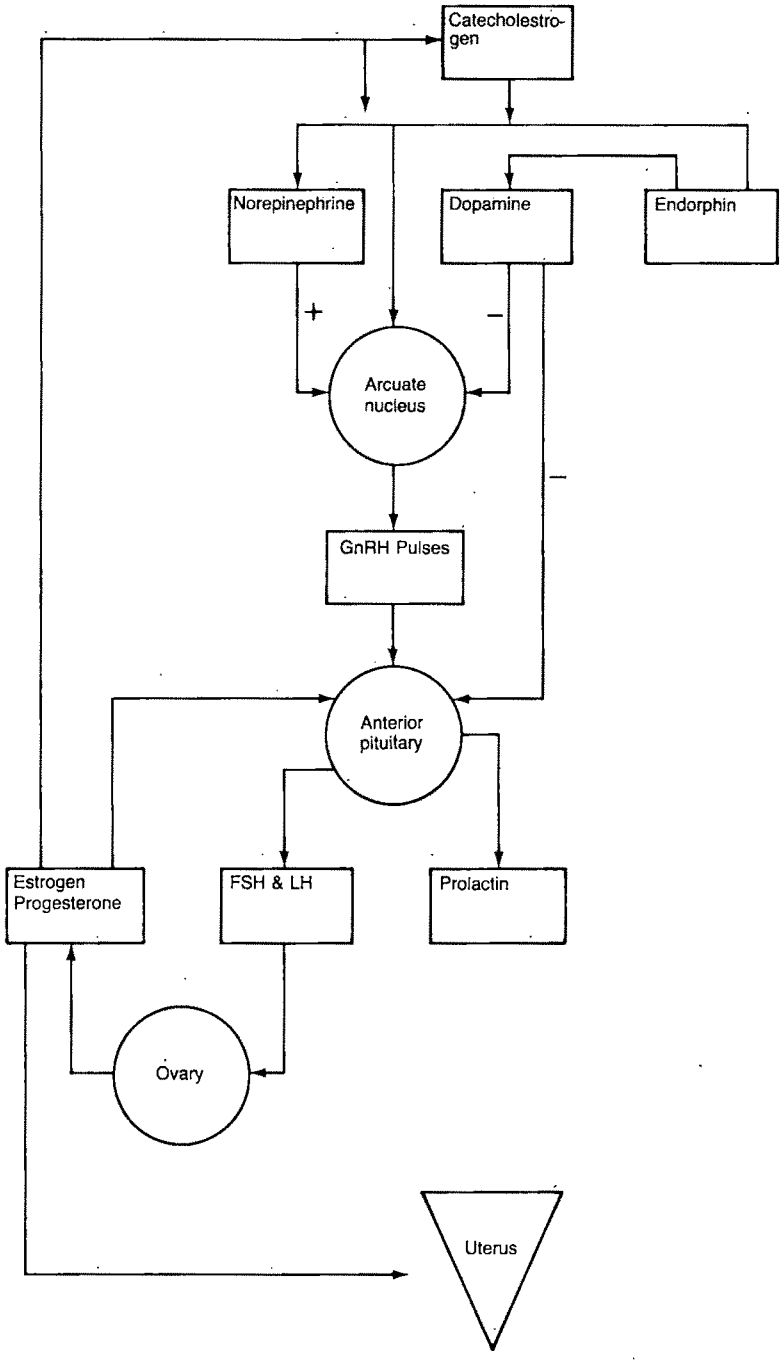

Fig. 1. Neuroendocrine control. (Reprinted with modification from Speroff L, Glass RH, Case NG. Clinical gynecological endocrinology and infertility. 3rd ed. Baltimore: Williams & Wilkins, 1983:56.) (*GnRH* = Gonadotropin-releasing hormone; *FSH* = follicle-stimulating hormone; *LH* = luteinizing hormone.)

ever, a short time later, reports of undesirable side effects and complications began to appear. By the late 1960s and early 1970s, there were multiple reports of serious complications including stroke, thromboembolism, and hypertension.[3-7]

In an attempt to reduce these adverse effects, the manufacturers reduced the steroid content and introduced new progestogens. Except for a brief trial with a sequential approach and the currently available minipill, all of the formulations have used a combined daily dose of progestogen and estrogen. Through the 1970s and 1980s, reduction of steroid content has continued, until now the preferred combination pill contains 1 mg or less of a progestogen and 30 to 35 μg of an estrogen.

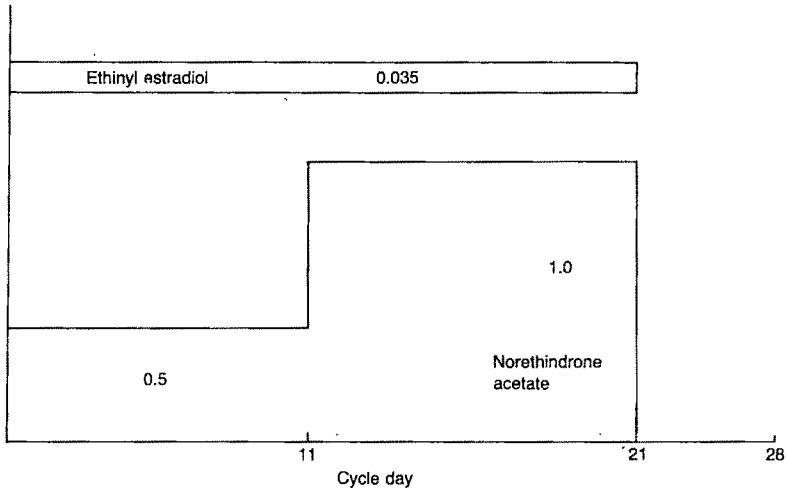

Fig. 2. Biphasic oral contraception.

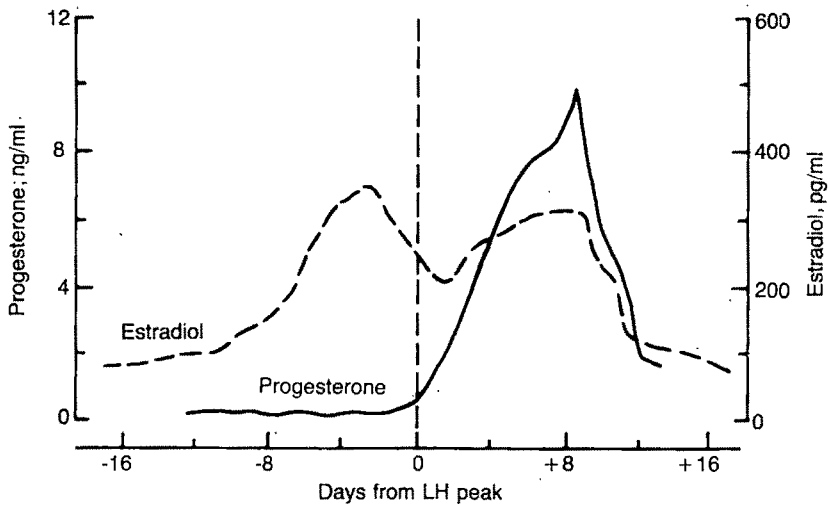

Fig. 3. Normal hormonal cycle.

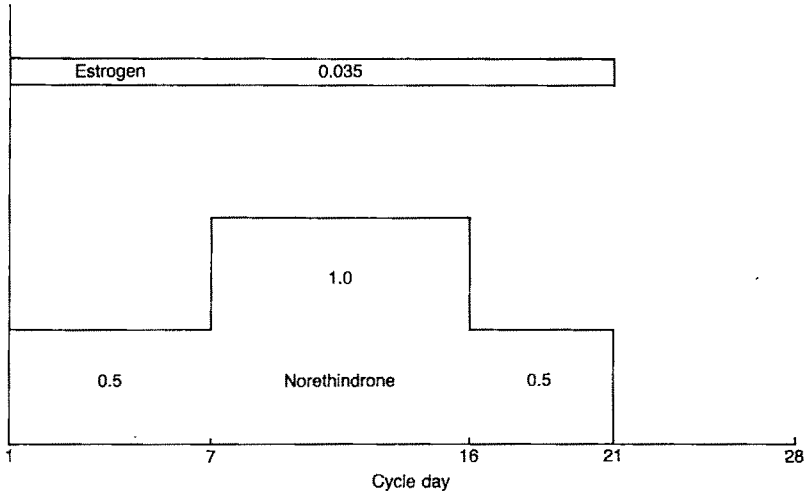

Fig. 4. Triphasic No. 1.

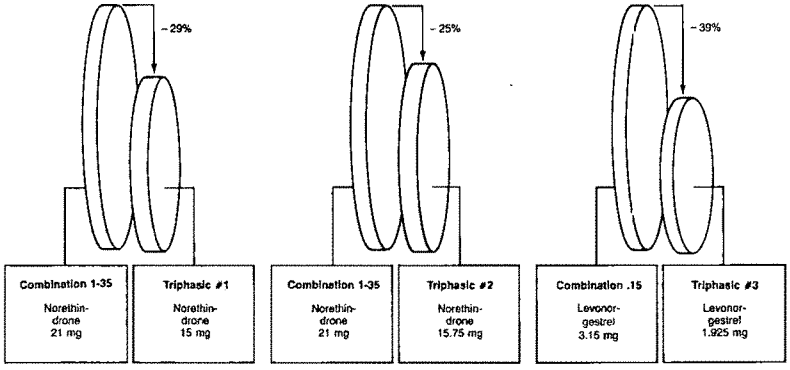

Fig. 5. Progestogen content compared with combination pill.

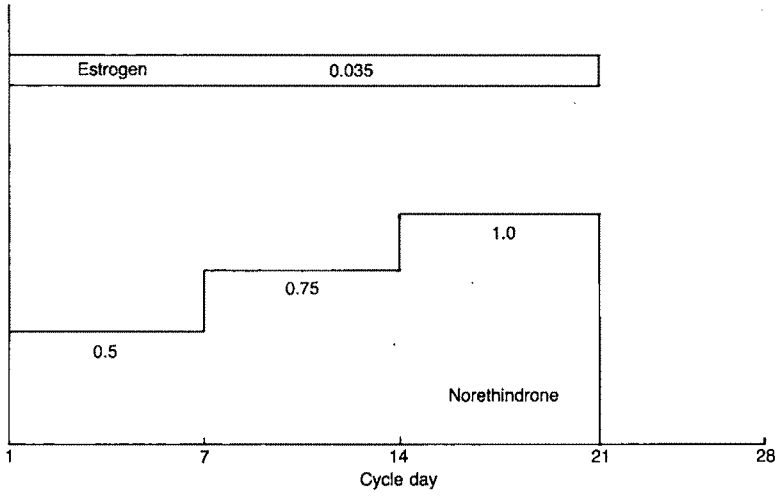

Fig. 6. Triphasic No. 2.

It is widely believed that these low-dose formulations have far fewer side effects and complications than do the earlier higher-dose pills.[8-10]

Recently, newer formulas have been introduced that attempt to lower the hormonal content of the average cycle even further. Although there is insufficient evidence to prove that the total steroid content of any given cycle is as important as the daily amount, it seems logical that any method that lowers the total amount of steroid ingested would be a positive step toward further reduction of complications and side effects.

The first of these newer pills was a biphasic pill. The patient took one fixed dose for the first 10 days of the cycle and another dose for the next 11 days (Fig. 2). This pill used two existing formulas and resembled the earlier sequential pill. However, this formulation had a high percentage of side effects such as breakthrough bleeding and offered very little to patients.

The next step forward was the development of a triphasic pill. In this formulation, the patient receives a different dosage schedule in each of three separate periods within the same cycle. I will discuss this type of approach to oral contraception in this paper.

Normal cycle control

To understand fully the principles of the phasic approach, it is necessary that we first review the hormonal pattern of the normal cycle. In this way, we can compare the natural with the controlled cycle (Fig. 3).

The initial event in any menstrual cycle is the menstruation that results from hormonal withdrawal, ischemia, and necrosis of the endometrium. At this phase of the cycle, estrogen production is at its lowest level. Estrogen gradually increases during the next 10 to 14 days and reaches a peak at the time of ovulation. This peak is followed by reduced production for the next 3 to 5 days. Estrogen levels then gradually rise and plateau until approximately day 24 or 25 when they drop to baseline. On the other hand, progesterone begins to rise 1 to 2 days before ovulation, reaches a peak

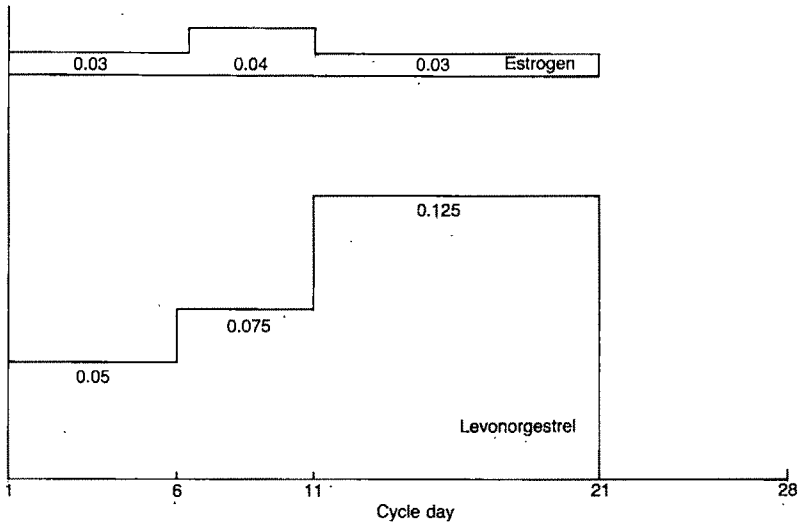

Fig. 7. Triphasic No. 3.

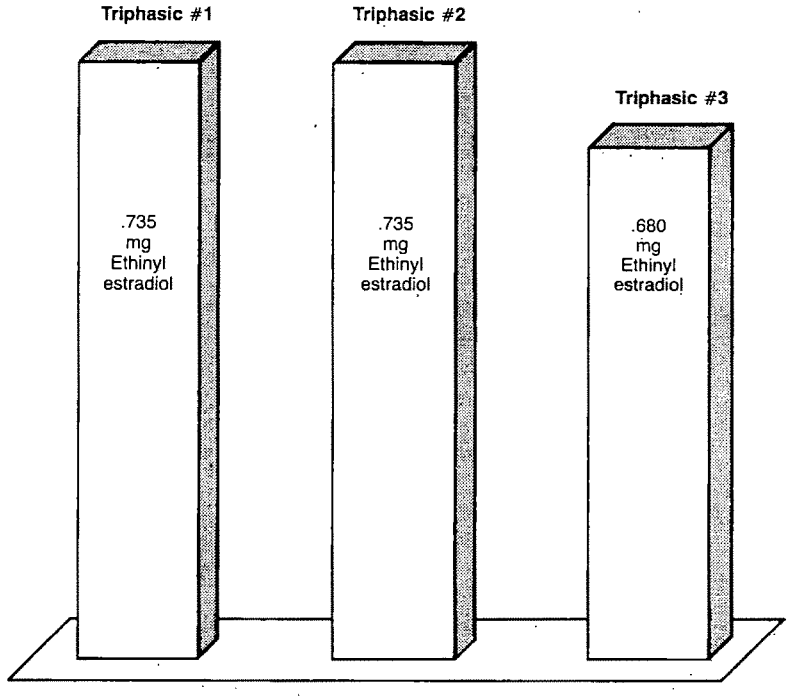

Fig. 8. Total estrogen content of triphasics.

on approximately day 19 or 20, and then begins to regress until it returns to baseline at day 28. The new triphasic pills attempt to imitate this cyclic rhythm.

Current preparations

Three triphasic formulations are marketed today. Each has been developed using a parent compound, currently marketed as an oral contraceptive, and then altering the hormonal content. In two of these three pills, the estrogen content, 0.035 mg of ethinyl estradiol, remains constant throughout the cycle whereas the progestogen content changes.

Fig. 4 shows how one of these formulations uses 0.5 mg of norethindrone for the first 7 days, followed by 9 days of 1 mg of norethindrone, and then returns to 5 days of 0.5 mg of norethindrone. The total steroid dosage is less in this formulation than in a 1/35 pill (Fig. 5), but the last 5-day reduction has led to early bleeding and difficulty with patient acceptance in my practice.

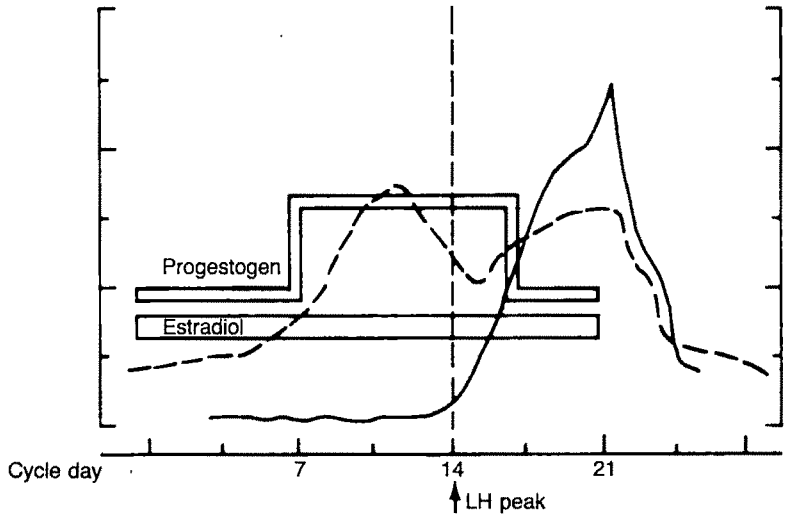

Fig. 9. Triphasic No. 1. (*LH* = Luteinizing hormone.)

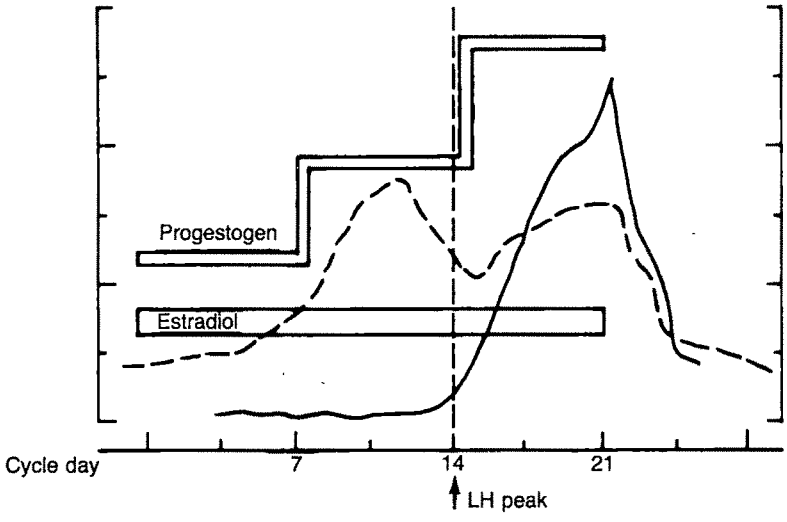

Fig. 10. Triphasic No. 2. (*LH* = Luteinizing hormone.)

A second formulation that uses the constant estrogen dose is seen in Fig. 6. This pill begins with 7 days of 0.5 mg of norethindrone, then increases to 0.75 mg of norethindrone for 7 days, and ends with 7 days of 1 mg of norethindrone. This formulation again gives a reduced hormone level compared with the typical 1/35 combination pill (Fig. 5).

The third triphasic preparation (Fig. 7) has a formulation different from the other two. Not only does this pill contain a different progestogen (levonorgestrel), it also alters the amount of estrogen and progestogen. In the first phase of this pill, the patient receives 0.03 mg of ethinyl estradiol and 0.05 mg of levonorgestrel for 6 days; for the next 5 days she receives 0.04 mg of ethinyl estradiol and 0.075 mg of levonorgestrel; during the last 10 days, the patient receives 0.03 mg of ethinyl estradiol again in combination with 0.125 mg of levonorgestrel. This formulation again reduces the total progestogen content of the cycle (Fig. 5). In addition, it also lowers the estrogen content compared with the other two triphasics (Fig. 8). The levonorgestrel triphasic is the only one of the three triphasic pills currently marketed that has been extensively studied as a triphasic.

The cycles of each triphasic are compared with the normal hormonal cycle in Figs. 9 through 11. Each of the three formulas has attempted to duplicate the normal cycle in a different fashion. Only one approaches the estrogen levels, and only two replicate the progesterone component.

In each of these formulations, the hormone content has been changed to give a reduced level of steroid.

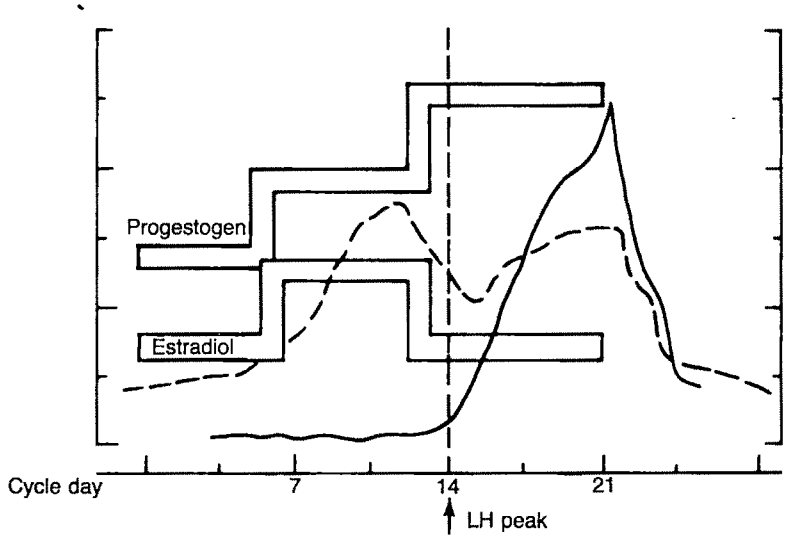

Fig. 11. Triphasic No. 3. (*LH* = Luteinizing hormone.)

Although the benefits of reduced total steroid content have yet to be proved, I believe that any attempt to reduce the total amount of steroid ingested during the cycle is potentially beneficial.[11] However, early reports show a slightly higher incidence of breakthrough bleeding than had been noted with the comparable fixed combination pill. This possibly reflects the reduced hormone level and indicates that we approach the lowest practical level with currently available steroids. On the other hand, early studies suggest that the levonorgestrel triphasic produces fewer alterations in metabolic pathways, lipid chemistry, coagulation profiles, and blood pressure. Other incidental side effects, such as acne, depression, and nausea, are also reduced.

In conclusion, the new phasic approach is an attempt to reduce the total steroid content and thereby reduce the negative impact of the "pill." It is also an attempt to emulate the normal menstrual cycle. For this reason, I believe that a triphasic pill of the physician's choice should be the initial agent for all patients desiring oral contraceptives.

New progestogens in oral contraceptives

Benno Runnebaum, M.D., and Thomas Rabe, M.D.
Heidelberg, West Germany

The aim of using new synthetic progestogens (gestodene and norgestimate) in oral hormonal contraceptives is to find a combination that has a more beneficial effect on metabolism and endometrium than presently available formulations. Our studies with low-dose pills containing 30 μg ethinyl estradiol/150 μg levonorgestrel or 30 μg ethinyl estradiol/150 μg desogestrel compared with the new pills with 35 μg ethinyl estradiol/250 μg norgestimate or 30 μg ethinyl estradiol/75 μg gestodene revealed no significant alterations of serum glucose after glucose loading. With all four combination pills, insulin levels were slightly elevated when compared with controls. Studies of the lipid metabolism showed that depending on the type and estrogen combination, progestogens have different effects on lipid metabolism. The new progestogens seem to have a more pronounced effect on triglycerides, whereas total cholesterol and high-density lipoprotein cholesterol remain almost unchanged. In general, it could be shown that low-dose oral contraceptives have little impact on lipid metabolism. Studies with low-dose monophasic preparations, including the new formulations, reveal only a low effect on blood coagulation. According to our and other data on the new progestogens in oral contraceptives available so far, it can be expected that such low-dose monophasic and triphasic combination pills will be beneficial during longtime use with respect to side effects on the cardiovascular system and control of the menstrual cycle. (Am J Obstet Gynecol 1987;157:1059-63.)

Key words: Oral contraceptives, low-dose monophasic preparations, insulin levels, lipid metabolism, blood coagulation

The effects of the various progestogens in oral contraceptive pills have been studied extensively.[1, 2] Although a complete evaluation of the many different actions of the synthetic progestogens is impossible at the present time, this article will attempt to describe and compare the effects of known progestogens with those of the new synthetic progestogens.

Structural characteristics

All synthetic progestogens are derivatives of either 17α-hydroxyprogesterone or 19-nortestosterone. The 19-nortestosterone derivatives can be categorized according to structure into the estranes and the biologically more effective gonanes. The estranes are chemically characterized by the absence of a methyl group between ring A and B and by an ethinyl group in position 17α. These substitutions delay the compounds' inactivation in the liver and greatly reduce the androgenic effects. The gonanes share these structural features and are also characterized by an ethyl group in position 13. Among the gonanes are the most effective new synthetic progestogens, such as levonorgestrel, desogestrel, norgestimate, and gestodene, which are the focus of this paper.

From the Division of Gynecological Endocrinology, Department of Obstetrics and Gynecology, University of Heidelberg.

Table I. Main effects of synthetic progestogens in women

1. Inhibition of ovulation
2. Secretory transformation of estrogen-primed endometrium; inhibition of the proliferative process
3. Effect on tubal secretion and egg transport; inhibition of myometrial contractions
4. Delay of menstruation in estrogen-pretreated women
5. Changes in composition of cervical mucus
6. Increase in glycogen storage in the endometrium
7. Decrease of karyopyknotic index of the vaginal epithelium
8. Maintenance of pregnancy
9. Influence on hepatic metabolism
10. Increase in basal body temperature
11. Relative binding capacity to various steroid hormone receptors

Spectrum of biologic effects

The different progestogens are absorbed differently in the gastrointestinal tract. They are partially metabolized in the liver, that is, activated, inactivated, or transformed into metabolites with other partial effects. The chemical structures of these compounds and the combination with estrogens determine not only their binding affinity to the steroid receptor but also their binding to serum proteins, their distribution and storage in the organism, and their metabolism in the target tissues.[3, 4] Furthermore, both receptor concentration and receptor affinity play important roles in determin-

Norethisterone	Triphasic	No significant effects on glucose and insulin		Rabe et al. (1985)[8]

ing biologic effect. The progestogens can competitively or noncompetitively accelerate or inhibit the activity of many enzymes, and in this way, change the metabolic processes in the target organ, the liver, or another organ.[3, 4] Finally, the effects of the progestogens depend on the synergistic influence of the estrogens. The estrogens induce the synthesis of the progesterone receptors and thus create the basis for progestogen action.[5] Estrogens are responsible for the proliferation of the endometrium, whereas progestogens lead to a transformation.

Because of the large number of progestogen effects, which are partly created synergistically with estrogen, it is very difficult to characterize a particular progestogen (Table I). General evaluation is based on whether the substance has a progestogenic, estrogenic, antiestrogenic, androgenic, or antiandrogenic effect. The various metabolic effects of a particular progestogen in combination with estrogen are also important.

The new progestogens are strongly progestogenic with respect to ovulation inhibition, endometrium morphology, binding affinity to the progesterone receptor, and pregnancy maintenance (Table II). Levonorgestrel and the new third-generation progestogens, such as

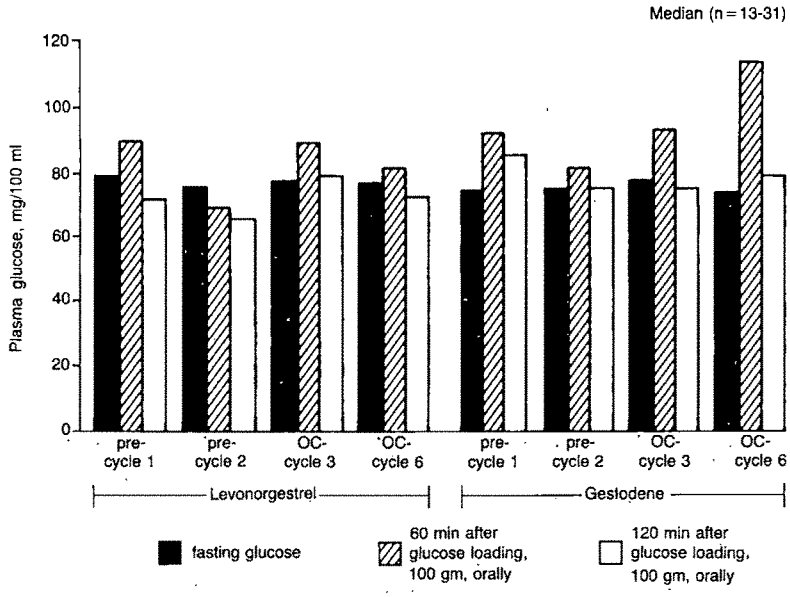

Fig. 1. Effects of levonorgestrel and gestodene on glucose response to a glucose load. (*OC* = Oral contraceptive.)

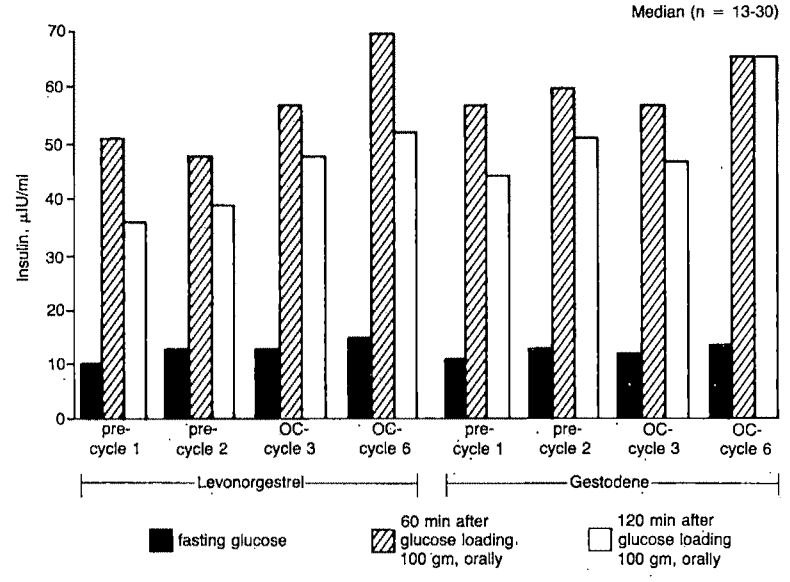

Fig. 2. Effects of levonorgestrel and gestodene on insulin response to a glucose load. (*OC* = Oral contraceptive.)

desogestrel, norgestimate, and gestodene, are real progestogens as judged by their pregnancy maintenance effects. They have no estrogenic effect, but, rather have pronounced antiestrogenic effects. Their androgenic effects are not clinically relevant, and they have no discernible antiandrogenic effects.

Carbohydrate metabolism

In comparing the influence of different oral contraceptives on carbohydrate metabolism (Table III), it is important to consider that factors independent of the pill, such as race, nutrition, and life-style, also play a role. Furthermore, the dosage, steroid content, and formulation of the particular pill may influence fasting glucose, glucose tolerance, kidney tolerance for glucose, and pancreatic insulin secretion. The effects of oral contraceptives on carbohydrate metabolism are assessed by measuring fasting glucose levels and performing an oral glucose tolerance test with measurements of glucose and insulin.[6-8] Pills containing the progestogens levonorgestrel and gestodene exert small effects on glucose and cause only minor increases in

insulin level (Figs. 1 and 2). It is difficult to determine whether a minor deterioration in glucose tolerance that is associated with long-term pill use actually represents a danger to health, especially the health of the cardiovascular system (Table IV).

Lipid metabolism

Lipid metabolism is an important aspect in analyzing cardiovascular risk associated with oral contraceptive use. However, it must be kept in mind that risk factors such as smoking, hypertension, hyperlipidemia, adi-

posis, diabetes mellitus, and cardiovascular illness play a decisive role. Furthermore, various influences of oral contraceptives on lipid metabolism must be considered. Unfavorable effects, especially on the concentration of high-density lipoprotein cholesterol, may be genetic, fat dependent, or influenced by smoking.

The new progestogens in monophasic pills have only a low impact on total cholesterol and high-density lipoprotein cholesterol levels (Fig. 3).[1, 2, 9, 10] However, they exert a distinct effect on triglyceride concentrations (Table V), although the clinical importance of this finding is as yet uncertain.

Blood pressure

Although estrogen-progestogen mixtures may affect blood pressure regulation, long-term clinical trials show that the new progestogens, such as norgestimate and especially gestodene, do not change blood pressure. Animal experiments have proved that gestodene favorably influences the renin-angiotensin-aldosterone system, and it is possible that these effects also occur in humans.

Coagulation

The exact extent to which progestogen type and dosage are responsible for changes in the blood clotting system has not been fully elucidated. Low synergistic or antagonistic effects of progestogens have been observed, depending on the partial antiestrogenic properties of the particular compound. The low-dose oral contraceptives have only a low impact on blood clotting.[11, 12]

Directions for future research

The pharmacologic and clinical profiles of the new synthetic progestogens, gestodene and norgestimate, have aroused much interest. In low-dose monophasic combination pills, these substances have only little effect on carbohydrate metabolism and different effects on lipid metabolism. The pronounced effects on triglyceride and phospholipid concentration must still be studied. The changes in the blood clotting system seem to be limited.

Some 5% of the healthy women who took part in our pill studies exhibited marked changes in certain parameters of lipid metabolism and blood clotting. Future studies of oral contraceptives might focus more attention on those persons in whom lipid metabolism or the blood clotting system reacts strongly to the pill.

To date clinical experience indicates that the new progestogens are well accepted by patients and are associated with a low (5% to 6%) incidence of spotting.

PART 2: ALTERNATIVE METHODS OF CONTRACEPTION

Introduction

Egon Diczfalusy, M.D.
Stockholm, Sweden

The development of alternative methods of contraception is reaching a watershed. Many of the theoretical innovations of the last decade are now being translated into practice in clinical trials.

The dynamism in today's contraception arena was evidenced by five progress reports presented during the second half of a Contraception Plenary Session at the XII World Congress of Fertility and Sterility in Singapore, October 28, 1986. One especially promising approach under investigation involves the use of antiprogesterones for fertility control. Still another cause for excitement is the fact that after a decade of intensive testing, four birth control vaccines are currently undergoing clinical trials. The male contraceptive gossypol also represents an interesting area, although further research will be necessary to determine whether associated toxicity can be circumvented at contraceptive doses. Natural family planning has evolved considerably, although it remains to be seen whether the use-effectiveness of this approach can be increased so as to match its high method-effectiveness. Yet another important advance, which promises to have worldwide application, is the long-acting subdermal levonorgestrel implant (Norplant).

The international developments discussed in these proceedings indicate that we have reason to be optimistic. As we approach the beginning of the next century, we should see a much broadened array of choices for couples desiring family planning assistance.

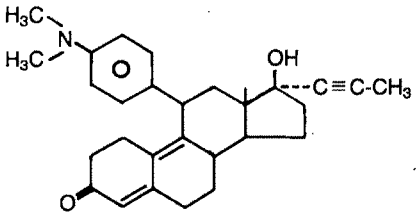
Endometrial and myometrial effects of progesterone antagonists in pregnant guinea pigs

W. Elger, M.D., M. Fähnrich, S. Beier, Ph.D., Shi Shao Qing, M.D., and K. Chwalisz, M.D.
Berlin, West Germany, and Beijing, China

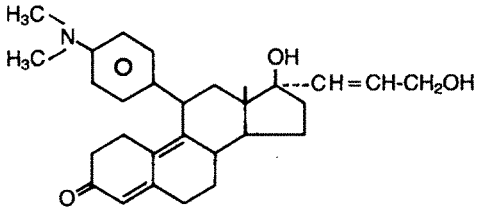
Three antiprogestogens of the RU 38.486 type, RU 38.486, ZK 98.734, and ZK 98.299, were studied at different stages of pregnancy in the guinea pig. Treatment starting on postconception day 4 completely prevented nidation; all three compounds had comparable inhibitory potency. Treatment after nidation, starting on postconception day 8, induced decidual collapse and bleeding, but embryonic tissue was retained in nidation sites. In contrast to results in animals in nonfertile cycles, luteolysis was not induced, indicating that antiprogestogens lack the ability to induce uterine prostaglandin synthesis/liberation. On postconception day 43, RU 38.486 showed marginal abortifacient activity. The other compounds induced expulsion more rapidly and at a higher rate. The comparatively pronounced antiglucocorticoid activity of RU 38.486 may account for this difference. With RU 38.486, a high level of uterine prostaglandin sensitivity and a cervical ripening were induced consistently and fast; spontaneous labor, on the other hand, occurred after several days, if at all. Complete uterine evacuation was induced within hours by otherwise inactive doses of sulprostone in various combinations with ZK 98.299 and RU 38.486 but surprisingly not with ZK 98.734. A single dose of ZK 98.299 induced an approximately thirtyfold increase in uterine prostaglandin sensitivity within 24 hours, exceeding that present before term, but did not induce spontaneous labor. This is evidence that endogenous prostaglandins were not activated, analogous to perinidation stages. Observation of antiluteolytic activity of antiprogestogens in nonpregnant animals is considered of major theoretical importance in this context. It seems that inhibition of progesterone leads to suppressed uterine prostaglandin liberation. The same effect in pregnancy could explain the inability of the uterus to expel a seriously compromised conceptus. In conclusion, we suggest that progesterone is a stimulator rather than a depressor of uterine prostaglandins in the late luteal phase and pregnancy. The ability of the conceptus to neutralize this stimulatory action of progesterone is considered to be essential for the rescue of the corpus luteum and uterine motor quiescence in the guinea pig. The clinical significance of these findings is that the high frequency of incomplete abortions and protracted, sometimes heavy bleeding in pregnant women treated with RU 38.486 may reflect decidual compromise and simultaneous uterine prostaglandin deficiency, as found in our animal model after progesterone blockage.
(AM J OBSTET GYNECOL 1987;157:1065-74.)

Key words: Antiprogestogens, effect in pregnant guinea pigs, myometrium, endometrium, prostaglandin synthesis/liberation



Csapo[1] theorized that the elimination of progesterone in pregnancy should automatically lead to pregnancy termination by explusion of the uterine contents. Since competitive progesterone antagonists became available as a result of the pioneering work performed by the scientists of Roussel-Uclaf,[2-4] it has become possible to reevaluate this concept critically in laboratory animals.

In spite of the confirmation of the abortifacient effects of RU 38.486 and other antiprogestogens in all evaluated animal species, certain phenomena require more detailed consideration. For example, in humans[5] these drugs often have produced incomplete abortions or have failed to induce expulsion as pregnancy advances.



The effects of different antiprogestogens of the RU 38.486-type can be quite different. In light of this, we studied the effects of three steroids—RU 38.486 and two chemically related compounds (Fig. 1)—in guinea pigs at different stages of pregnancy. Compared with RU 38.486, the other two compounds have, among other alterations, side-chain modifications that consistently reduce their antiglucocorticoid activity.[6] A reduction in this activity may provide better tolerance.

In addition, there is some evidence of an interaction between the progesterone-antagonistic and antiglucocorticoid activity of these drugs at the uterine level. RU 38.486, as assessed by antithymolytic activity, has more antiglucocorticoid activity than the other two compounds. ZK 98.734 is the least active in this respect. It is important to note that oral administration of all three drugs leads to an *elevation* of antiglucocorticoid activity but no simultaneous increase in progesterone-antagonistic activity.

Fig. 1. Chemical structures of tested antiprogestogens.

Inhibition of nidation

Antiprogestogen treatment prevented nidation on postconception days 4 to 6, that is, before the day of nidation. A collapse of nidation sites was induced by treatment on days 8 to 11 of pregnancy. These effects were superior to those of castration, which does not terminate pregnancy at these early stages.[7] In guinea pigs, there seems to be embryonic progesterone secretion at the latest by the time of nidation, which permits nidation in the absence of luteal progesterone. The progesterone antagonists may be superior to castration due to their ability to neutralize this trophoblastic progesterone in addition to antagonizing luteal progesterone.

At both investigated perinidation stages, we found that maximum effects of all tested steroids were achieved at a dose of 10.0 mg/animal/day with subcutaneous administration. At a dose of 1.0 mg, there were no inhibitory effects. Incomplete and variable effects were seen at a dose of 3.0 mg; this finding suggests that 3.0 mg is the threshold dose for all three compounds.

This more or less comparable activity of the three steroids is in distinct contrast to their effects in later stages of pregnancy. Important additional information with regard to the mode of action was obtained from histologic investigations and the evaluation of serum progesterone. Histologic examination revealed that embryonic tissue was still present at degenerating nidation sites. This finding of incomplete abortion indicates that myometrial activation and mechanical evacuation did not take place. Furthermore, lack of effect of antiprogestogens on serum progesterone levels suggests that they did not induce uterine prostaglandin liberation, which would have exerted a luteolytic effect[8,9] (Fig. 2).

Myometrial effects of prostaglandins and antiprogestogens

The guinea pig model. This species was selected primarily because of some physiologic similarities to human pregnancy, for example, a luteoplacental shift of progesterone secretion and a high level of circulating progesterone until parturition. On postconception day 40, castration or luteolysis is possible without consequent abortion.

Moreover, we found an analogy between the uterine motor responses of the pregnant guinea pig to natural and artificial prostaglandins and those in human pregnancy.[10] Uterine motor activation leading to expulsion could also be achieved in the presence of high circulating progesterone levels. In this respect, the guinea pig was similar to monkeys but different from rats, in which the effects of the prostaglandin sulprostone on pregnancy were abolished by exogenous progesterone. The guinea pig model was very important for the discovery of sulprostone.[11]

The guinea pig uterus can be triggered to expel its contents at the earliest on day 20 of pregnancy. From this point, the oxytocin sensitivity increases progressively until it has risen by a factor of approximately 100

at parturition. The sensitivity for prostaglandin E_2 (PGE_2) and sulprostone increases mainly after day 40 by a factor of 10.

No such trend was seen for prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$). The dose-response curves of $PGF_{2\alpha}$ were practically the same in the early, middle, and late stages of pregnancy. From this we conclude that PGE_2 and $PGF_{2\alpha}$ have different roles in the activation of the quiescent myometrium. We believe that $PGF_{2\alpha}$ is the "terminal" prostaglandin and that PGE_2 may act as a trigger for $PGF_{2\alpha}$.

Another aspect of pregnancy in the guinea pig that is analogous to human pregnancy is the development of practically absolute estrogen resistance around day 20. Around day 40, even 10 mg of estradiol was tolerated; only the rate of dead fetuses was raised.[12]

Antiprogestogens alone. The first steroid in our hands that was able to induce abortion by expulsion in advanced pregnancy in the guinea pig was RU 38.486. As can be seen in Fig. 3, several days elapse before expulsions occur. In this experimental situation, important differences emerged between the tested compounds. In the case of RU 38.486, we found that even very high doses, such as 30.0 mg/animal/day administered subcutaneously, failed to induce expulsions in more than 50% of the animals. On the other hand, ZK 98.734 showed dose-dependent effects and was faster acting than RU 38.486. All the animals aborted at the highest tested dose of 30.0 mg/animal/day administered subcutaneously.

The evaluation of oral activity confirmed these differences among the three compounds. We often observed a fall in the dose-response curve at high doses. At the highest tested dose of RU 38.486, only one out of six animals aborted. Most of those animals that did abort had prolonged abortions. Our studies with prostaglandin combinations (see below) indicate that low oral bioavailability of RU 38.486 probably does not account for this low activity.

Antiprogestogen/prostaglandin combinations. The low level of effectiveness of RU 38.486 and the long latency of expulsions compared with those after sulprostone prompted us to evaluate antiprogestogen/prostaglandin combinations. We studied both simultaneous and sequential treatments. Sulprostone was formulated in oil for simultaneous treatment (0.03 mg/day administered subcutaneously). For sequential treatment, a single 0.1 mg dose of sulprostone in saline solution was given 24 hours after the last antiprogestogen dose.

There were strong synergistic effects between some of the antiprogestogens and sulprostone. For example, a much higher number of animals aborted after simultaneous administration of RU 38.486 and marginal sulprostone doses than after administration of the progesterone antagonist alone. In addition, expulsion occurred much earlier after the combination (Fig. 4).

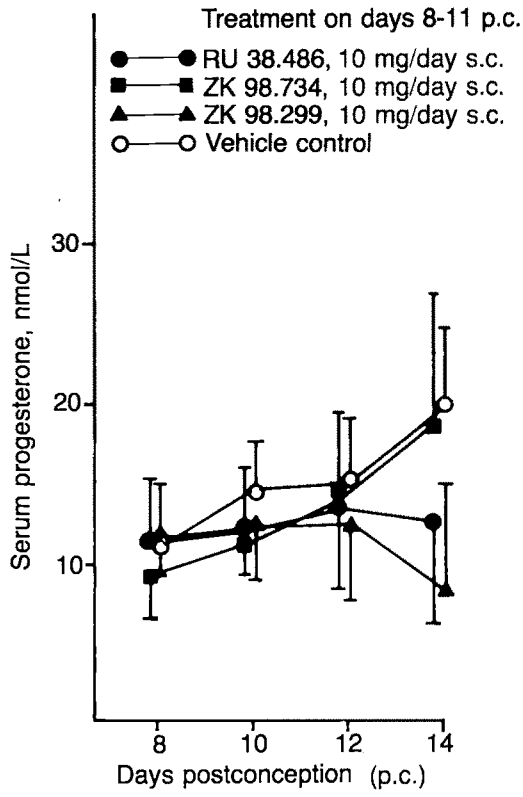

Fig. 2. Serum progesterone levels in aborting guinea pigs.

Surprisingly, this synergism did not apply to all substances to the same extent. In particular, ZK 98.734, which was fairly active when given alone at a dose of 3.0 mg/day administered subcutaneously, was not distinctly more active or faster acting when given in combination with sulprostone. On the other hand, even marginally active doses of RU 38.486 were synergistic.

Sulprostone treatment after antiprogestogen priming tended to lead to the rapid onset of expulsive behavior and the expulsion of conceptuses within a few hours. For example, supplementary sulprostone treatment after RU 38.486 and ZK 98.299 resulted in expulsion of conceptuses within 6 hours.

The different behavior of the above compounds was also confirmed in this sequential design. Again, ZK 98.734 induced expulsion at approximately the same time (most often, more than 48 hours after the last dose) with or without the prostaglandin.

The same pattern was seen after subcutaneous and oral application of the progesterone antagonists RU 38.486 and ZK 98.734. These data also show that RU 38.486, which is not very active when given alone orally, is fully active when combined with sulprostone (Fig. 5).

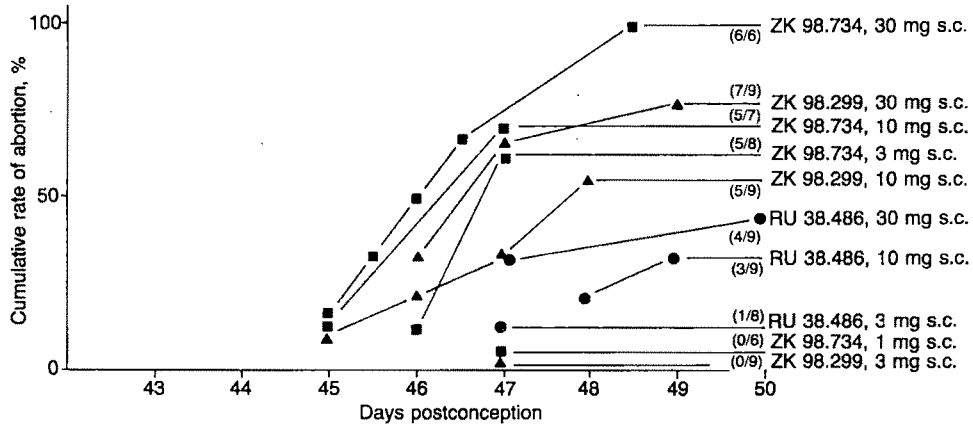

Fig. 3. Cumulative rate of abortions in guinea pigs after antiprogestogen treatment on postconception days 43 and 44.

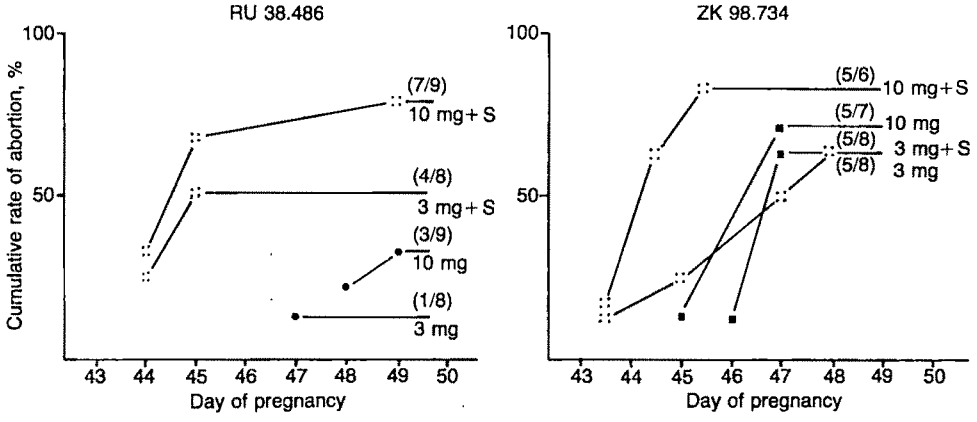

Fig. 4. Simultaneous antiprogestogen/sulprostone *(S)* (3 mg) treatment in guinea pigs; treatment was on postconception days 43 and 44.

Quantitative assessment of myometrial prostaglandin sensitivity. ZK 98.299 was found to be the most synergistic of the three compounds. Its activity was extraordinary in simultaneous and sequential combination regimens.

In order to establish the optimum duration of antiprogestogen priming, we compared the effects of 1 day's and 2 days' priming with a standard dose of 10.0 mg of ZK 98.299 per day administered subcutaneously and graded doses of sulprostone, injected 24 hours after the last antiprogestogen dose. There was no difference between the 1 day's and the 2 days' priming. This means that the uterus was completely sensitized within 24 hours. Above a well-defined threshold dose of sulprostone (that is, 0.01 mg administered subcutaneously), rapid expulsions and complete abortions occurred within 8 hours. This corresponds to an elevation of sulprostone sensitivity by a factor of 30 (Fig. 6). This uterine responsiveness is at least three times higher than that established in the immediate prepartum period (treatment on postconception days 63 and 64).

This dramatic myometrial sensitivity to the single ZK 98.299 injection was in sharp contrast to the absence of spontaneous abortion when subthreshold doses of prostaglandin were given. These data and those obtained with RU 38.486 demonstrate that some progesterone antagonists induce an "explosive" responsiveness of the myometrium long before the onset of "spontaneous" contractions, which may fail to occur at all.

This sequence of events is strong evidence that there is neither a preexisting "intrinsic uterine stimulant" nor sufficient activation of uterine prostaglandin to induce uterine contractions. Rather, our data suggest that uterine prostaglandins remain deeply suppressed for a couple of days. The failure to increase suppressed uterine prostaglandin secretion seems to us the key problem in understanding antiprogestogen actions in pregnancy.

Role of the glucocorticoid receptor in myometrial activation. In addition to the open question concerning antiprogestogen stimulation of uterine prostaglandins, the different behavior of antiprogestogens in the "myometrial" model used remains to be clarified. It seems un-

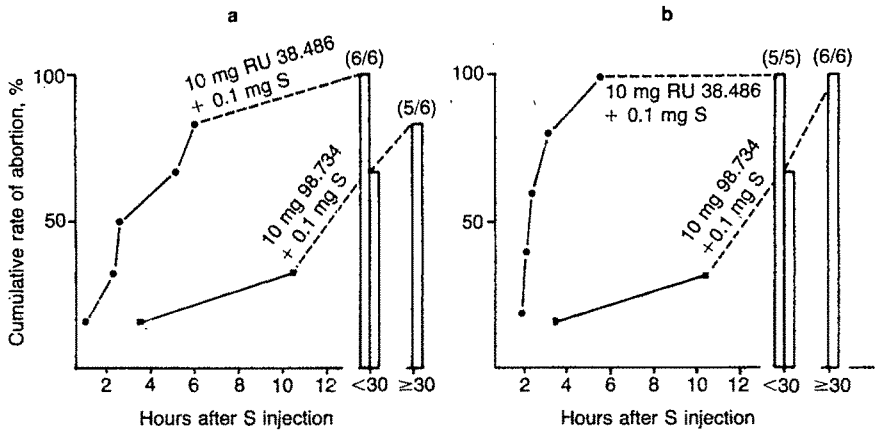

Fig. 5. Sequential antiprogestogen/sulprostone *(S)* treatment in guinea pigs: *(a)* subcutaneous application; *(b)* oral application. Antiprogestogen was given on postconception days 43 and 44; sulprostone, on postconception day 45.

likely that progesterone-antagonistic activity alone accounts for the different effects of the three compounds on myometrial prostaglandin sensitivity and the spontaneous onset of contractions.

We hypothesized that the interaction between the antiglucocorticoid activity and the progesterone-antagonistic activity of these drugs is favorable to myometrial sensitization and inhibitory to a later spontaneous onset of labor. This could explain the particular pattern of effects of RU 38.486.

In this context, we investigated the effects of dexamethasone in the guinea pig model in order to overcome the antiglucocorticoid activities of the antiprogestogens. Surprisingly, we found that dexamethasone inhibits the effects of sulprostone alone and reduces the activity of the antiprogestogens alone but increases the activity of the antiprogestogen/sulprostone combination. The onset of labor was advanced by approximately 24 hours. In the case of ZK 98.299, this combination brought about 100% abortions within 24 hours.

These data point to a potential role of the glucocorticoid receptor in myometrial activation. The nature of these effects is unknown, however, and the differences in the three compounds are not fully explained by their antiglucocorticoid activity.

Pilot studies with uterine pressure recordings. Intrauterine pressure was recorded in some animals during stimulation with oxytocic agents after antiprogestogen priming. This was done in conscious, freely moving animals after surgical intrauterine insertion of a microballoon, which was connected to a pressure tranducer by a fine polyethylene tube.

The individual data of these experiments must be regarded with some caution. Antiprogestogen-primed uteri were found to be extremely sensitive to mechanical irritation. Abortions were often recorded immediately after the operation. We found it necessary to insert the balloon before antiprogestogen treatment. Even this prompted expulsions before the expected time compared with the response in intact animals.

Nevertheless, we made some interesting observations

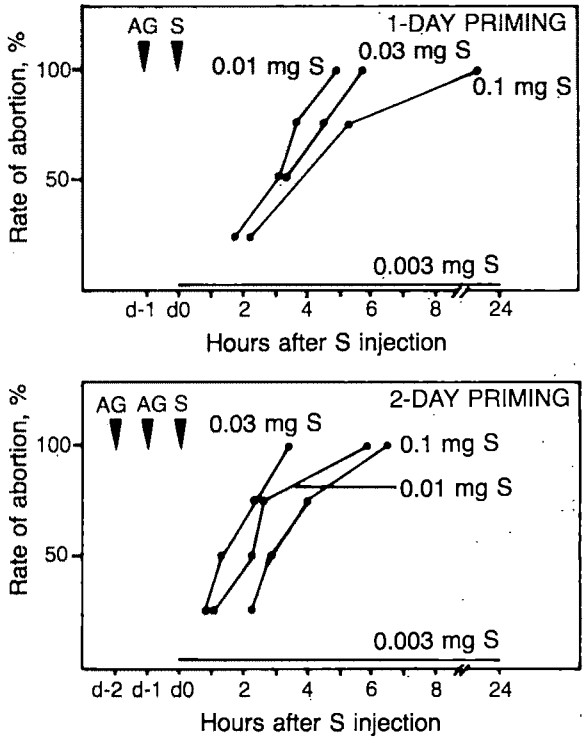

Fig. 6. Quantitative evaluation of uterine prostaglandin sensitivity in guinea pigs: priming with 10 mg of ZK 98.299 administered subcutaneously on postconception day 43 or days 43 and 44; single sulprostone injection administered subcutaneously 24 hours after last antiprogestogen *(AG)* injection.

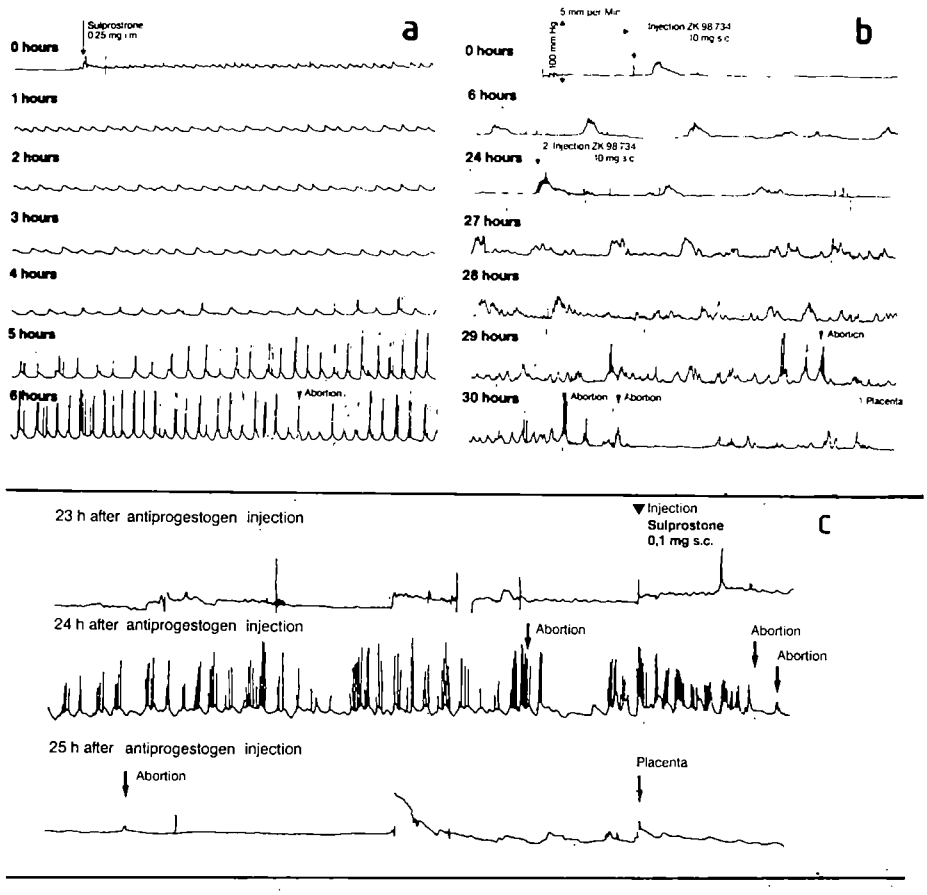

Fig. 7. Intrauterine pressure recordings in pregnant guinea pigs on postconception day 43 ± 1: *(a)* after a single sulprostone injection, *(b)* after two ZK 98.734 injections, and *(c)* with open silicone rubber catheter after priming with 10 mg of ZK 98.299 administered subcutaneously.

(Fig. 7). We found that a single injection of sulprostone induced very regular contractions after an initial elevation of resting intrauterine pressure. These led to an abortion within 6 hours.

Twenty-four hours after ZK 98.734 injection, there were irregular, very low-frequency contractions that lasted for several minutes and generated high intrauterine pressure. Expulsion occurred 30 hours after the first antiprogestogen treatment after a short phase of abdominal wall contractions (see spikes on Fig. 7, *b*) associated with uterine contractions.

Using a less traumatic device, namely, an open, fine silicone rubber tube, we recorded no spontaneous contractions 1 day after injection of 10.0 mg of ZK 98.299. A single 0.1 mg dose of sulprostone administered subcutaneously induced labor immediately and the expulsion of the first fetus within 1 hour.

This pattern is similar to the observations we made in intact animals; that is, the myometrium is highly responsive to stimuli but nevertheless quiescent. The very short duration of labor shows that the mechanical resistance of the genital tract is quite low. This will be explained by the effects of antiprogestogens at the level of the cervix (see below).

Satellite studies of $PGF_{2\alpha}$ in uterine vein blood and amniotic fluid. $PGF_{2\alpha}$ was estimated by radioimmunoassay in the plasma of uterine vein blood and in amniotic fluid at three times: before and after antiprogestogen treatment and at autopsy 6 hours after a final injection of a prostaglandin (PGE_2 or sulprostone) or at abortion. It was found that the repeated laparotomies had no effect on basal $PGF_{2\alpha}$ concentrations. There was also no consistent effect on basal $PGF_{2\alpha}$ levels in the two compartments after antiprogestogen treatment. A distinct elevation of $PGF_{2\alpha}$ was seen after the PGE_2 stimulation in vehicle-pretreated animals. This response was somewhat blunted in antiprogestogen-primed animals[13] (Fig. 8).

After ZK 98.734, the $PGF_{2\alpha}$ response seems to be particularly diminished. In spite of these comparatively low $PGF_{2\alpha}$ levels, however, some of the ZK 98.734–primed animals aborted. In contrast, the vehicle-

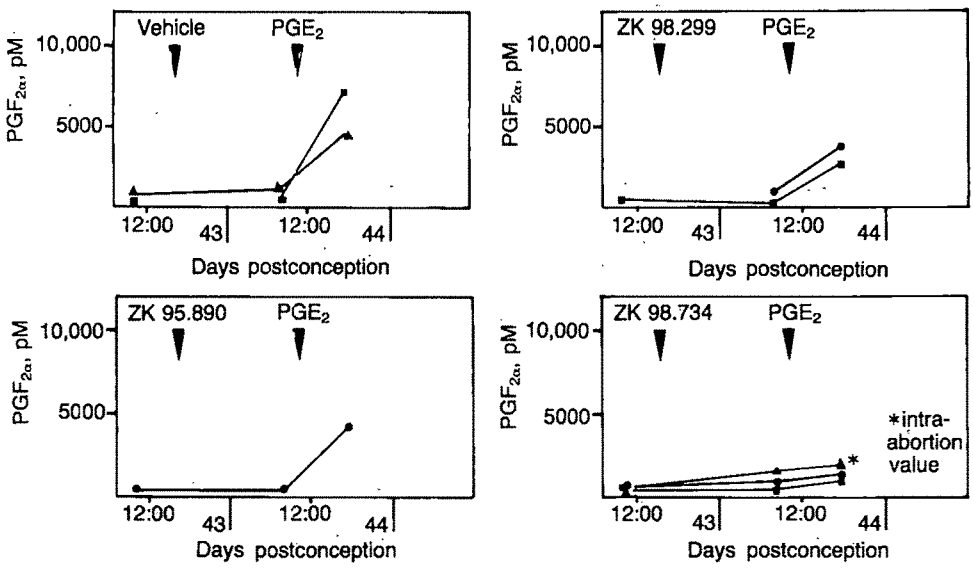

Fig. 8. Representative individual $PGF_{2\alpha}$ values in uterine vein plasma in pregnant guinea pigs (postconception days 43 and 44) after treatment with antiprogestogens (10.0 mg administered subcutaneously) and PGE_2 (1.0 mg administered subcutaneously).

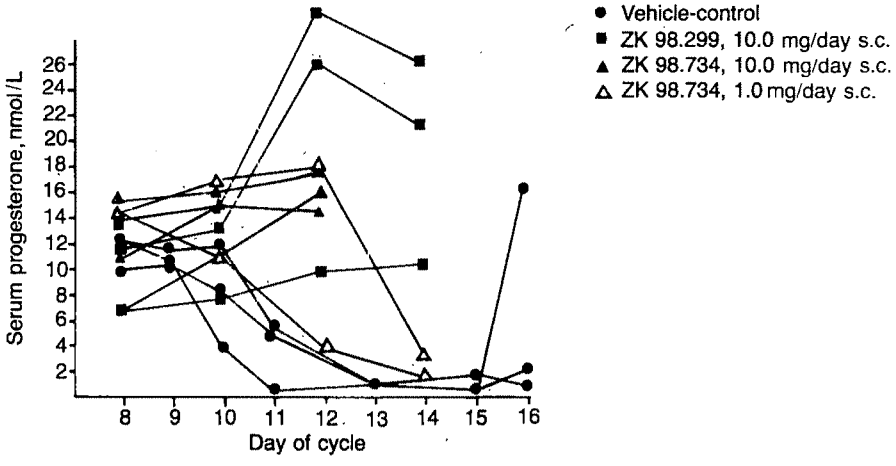

Fig. 9. Dose-dependent antiluteolytic effects of antiprogestogens in nonpregnant guinea pigs treated on days 8 to 11 of the cycle.

pretreated animals did not abort after exogenous prostaglandins until autopsy despite relatively high $PGF_{2\alpha}$ levels in uterine vein plasma.[13]

Antiluteolytic effects of antiprogestogens in nonpregnant guinea pigs. The described paradox, that is, maximum elevation of myometrial sensitivity associated with an absence of "intrinsic uterine stimulants," may have a surprising explanation. In the inhibition of nidation studies previously mentioned, some nonpregnant female animals were treated with antiprogestogens on days 8 to 11 of the cycle. The measurement of serum progesterone by radioimmunoassay revealed that in these ZK 98.299– and ZK 98.734–treated animals, the expected drop in progesterone levels at the end of the luteal phase did not occur (Fig. 9). Instead, these animals showed a pattern of serum progesterone that is typical of pregnancy. A study performed to check the validity of this observation confirmed the suspected antiluteolytic effects of ZK 98.299 in the guinea pig.[14] The dose-dependent antiluteolytic activity of ZK 98.734 and RU 38.486 has since been confirmed as well.

There is evidence in the literature that uterine prostaglandin, liberated by the nonpregnant uterus, destroys the corpora lutea in a nonfertile cycle. The inhibitory action of antiprogestogens on this event may

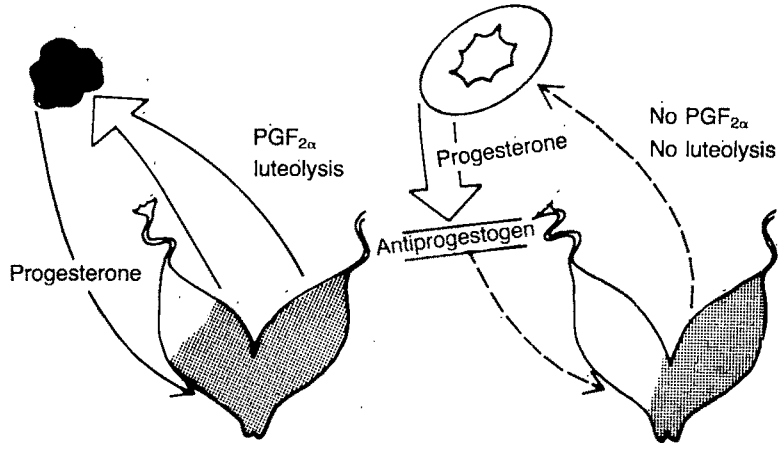

Fig. 10. Mechanism of antiluteolytic action of antiprogestogens: inhibition of progesterone-induced prostaglandin secretion.

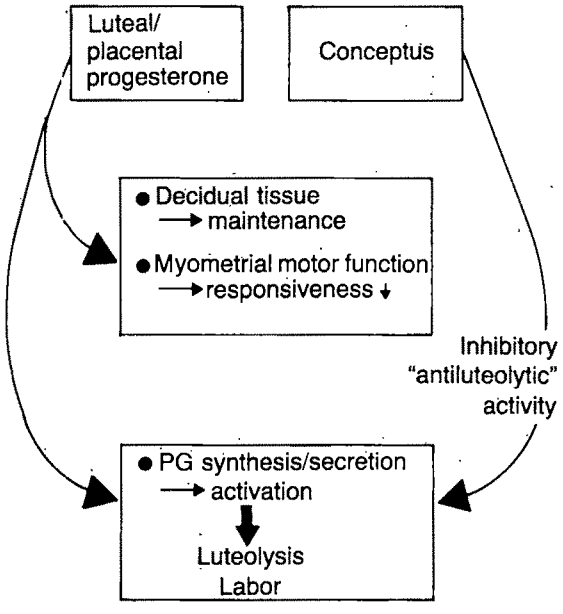

Fig. 11. Postulated paradoxical functions of progesterone in pregnancy.

therefore be explained as the inhibition of uterine prostaglandin liberation (Fig. 10).

If this action, rather than a direct or indirect luteotropic effect, does in fact occur, important questions arise about the role of progesterone in the control of uterine prostaglandins. As a hypothesis, we may assume that progesterone is a stimulator of uterine prostaglandins. The depression of uterine prostaglandins in pregnancy may be a function of the embryo, which first becomes manifest as its well-established antiluteolytic activity. Progesterone may represent a permanent stimulus of uterine prostaglandin generation in pregnancy that is under permanent embryonic suppression (Fig. 11).

Consequently, blockade of uterine progesterone in advanced pregnancy can be assumed to lead to suppressed prostaglandin generation; this is analogous to the events that take place during the luteal phase in a nonfertile cycle. This suppression of prostaglandins could lead to the inhibition of uterine motor activity as a result of the absence of an essential triggering mechanism, that is, uterine prostaglandins. A simultaneous collapse of decidual tissue, causing bleeding and myometrial sensitization, resulting from progesterone withdrawal at these target tissues would complete the observed "antiprogestogen syndrome."

Cervical effects of antiprogestogens in pregnant animals. There was a very rapid expulsion of conceptuses after sulprostone stimulation in antiprogestogen-primed animals. A ripening of the cervix, demonstrated by opening of the cervix and softening of cervical tissue, obviously plays an important role in this event. These changes were visible at vaginal inspection and were objectively measured in vitro.

We found spontaneous increases in the diameter of the cervix in the course of pregnancy, with marked preterm changes. There was a parallel softening of tissue, as assessed by reduced tension under stepwise extension. A dramatic dilatation and a softening of the cervix were recorded within 24 hours after a single dose of ZK 98.299 on day 43. Similar changes occurred even more rapidly around day 60 of pregnancy (Fig. 12).

Observation of the animals revealed other alterations in the birth canal, such as relaxation of the pelvic ligaments and opening of the symphysis pubis. These findings imply that relaxin may be a mediator of these effects.

We consider the observed effects of antiprogestogens at the cervix to be of potential clinical importance, in particular, for pregnancy termination at advanced stages or for the induction of parturition at term. It

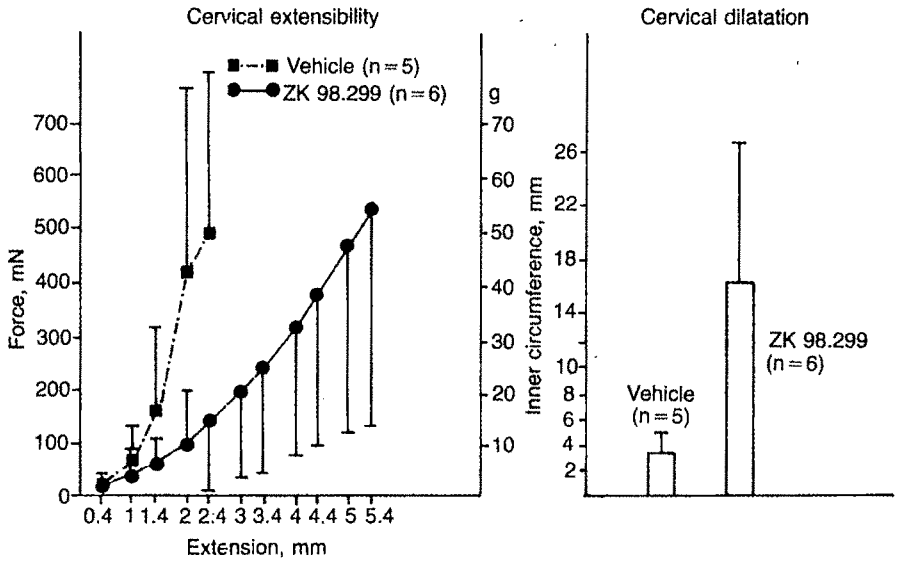

Fig. 12. Cervical extensibility and dilatation in pregnant guinea pigs after treatment with 0.3 mg of ZK 98.299 administered subcutaneously on postconception day 59, 5 to 6 PM; autopsy was performed on postconception day 60, 9 to 10 AM.

seems of particular importance that these effects can be obtained without simultaneous stimulation of uterine contractions.

Comment

Antiprogestogens were found to have important effects in various tissues in the pregnant uterus. Most of the observed effects on endometrial functions, such as prevention of nidation or collapse of nidation sites, are well explained by the known role of progesterone in nidation.

A less clear picture was obtained with regard to those functions that are related to myometrial motor activation, that is, the development of myometrial responsiveness to oxytocic stimuli on the one hand and the absence of endogenous stimuli that trigger the onset of labor on the other. Our studies revealed a rapid, dramatic elevation of myometrial responsiveness to exogenous prostaglandin and also to oxytocin, but there was no corresponding tendency of the uterus to go into labor spontaneously.[15]

This finding is in distinct contrast to the concept of Baulieu and Ulmann.[16] They postulated an increase in uterine prostaglandin as a consequence of the RU 38.486–induced blockade of the progesterone receptor and as a result of secondary effects, which lead to a decline in luteal progesterone production in humans, that is, a compromise of the conceptus and declining levels of chorionic gonadotropin.

On the basis of our data, we postulate exactly the opposite, the inhibition of uterine prostaglandin generation by progesterone-antagonistic activity. This seems to be reflected by a persistent suppression of uterine prostaglandin.

This notion is based on the absence of luteolysis in aborting animals in early pregnancy, the failure of highly sensitized uteri to go into labor, and the unchanged $PGF_{2\alpha}$ levels in uterine vein blood and amniotic fluid after antiprogestogen treatment. Inhibition of expected uterine $PGF_{2\alpha}$ liberation is evidenced by the clear antiluteolytic effect of antiprogestogens in the luteal phase in nonpregnant animals[14] and the blunted $PGF_{2\alpha}$ response after a PGE_2 or sulprostone stimulus in pregnant animals.[13]

The occurrence of "spontaneously" occurring expulsions after antiprogestogen treatment may not necessarily argue against the supposition of depressed uterine prostaglandin synthesis due to RU 38.486–type antiprogestogens. The abortions occurred quite late after treatment. At this time, there may be secondary changes, such as necrosis of decidual and trophoblastic tissue, and inflammatory responses that possibly coincide with stimulatory prostaglandin generation, independent of specific uterine control mechanisms.

It could also be of interest to investigate the pharmacokinetics of the tested compounds in relation to the established different time courses of expulsion.

If our assumptions—that uterine prostaglandin liberation is blocked by antiprogestogens and that this is due to their progesterone-antagonistic activity—are correct, it would be necessary to reconsider the role played by progesterone in the endocrine control of pregnancy. Its "classical" actions, namely, the lowering of myometrial responsiveness and the maintenance of

the nidation site, would be complemented by a paradoxical stimulatory activity on uterine prostaglandin liberation. This would imply that progesterone may have the potential to terminate a nonfertile cycle in the guinea pig or to stimulate uterine contractions unless embryonic inhibition overcomes this action (Fig. 11).

The cervical effects of antiprogestogens probably contribute greatly to the observed synergistic action of antiprogestogens and sulprostone by decreasing the mechanical resistance of the genital canal to the expulsive force of the uterus. The softening and opening of the cervix were also found to occur within a few hours. More pronounced and more rapid effects were found in preterm pregnancy than around day 40.

We infer from parallel observations of symphyseal changes that relaxin may be involved as a mediator of these responses. An elevation of relaxin levels may also be important in the depression of oxytocin secretion and the further inhibition of uterine contractility under antiprogestogens. Antiprogestogens appear to induce ripening of the cervix without stimulating myometrial contractions. This characteristic may be important in the potential use of antiprogestogens for therapeutic induction of abortion in advanced pregnancy or in obstetrics.

We suggest that the pattern of effects observed in clinical trials with RU 38.486 alone,[5] frequently ending in protracted bleeding and incomplete abortion, and in combination with sulprostone,[4] showing a strong antiprogestogen/prostaglandin synergism, is analogous to the effects we observed in midpregnancy in the guinea pig. This seems to be a good model for human pregnancy, particularly with regard to myometrial motor activation. Several potential approaches may be derived from the guinea pig model that could lead to the development of highly effective methods for medicinal pregnancy termination or for the induction of parturition.[17] This applies both to the selection of appropriate antiprogestogens to be used alone or appropriate antiprogestogen/prostaglandin combinations and to the design of treatment regimens that may arise from a better understanding of uterine physiologic and pharmacologic characteristics.

Recent developments in immunocontraception

G. P. Talwar, D.Sc., and Amitabh Gaur, Ph.D.
New Delhi, India

The possibility of controlling fertility by antibodies inactivating key reproductive hormones has been amply demonstrated by active and passive immunization in primates. Four birth control vaccines directed against human chorionic gonadotropin are currently in early clinical trials. The nature of these vaccines and the underlying principles are described, as are the available results from clinical studies. The α- and β-subunits of human chorionic gonadotropin and the ovine gonadotropins have been cloned by recombinant deoxyribonucleic acid methods. A new breed of vaccines that combines the genes of gonadotropins linked to hepatitis B surface protein has been developed. The next generation of birth control vaccines is likely to be polyvalent and to have the ability to intercept fertility at more than one point. A number of monoclonal antibodies against human sperm have shown the presence of tissue-specific antigens and the possibility of preventing the fertilization of the egg. Inclusion of more than one carrier in the vaccine increases the percentage of high responders and accords immunoprophylactic benefits against more than one disease. Conjugates have also been developed to obtain high titers of antibodies against gonadotropin-releasing hormone with permissible adjuvants. This vaccine may have therapeutic applications in hormone-dependent cancers and precocious puberty. (AM J OBSTET GYNECOL 1987;157:1075-8.)

Key words: Immunocontraception, vaccines against human chorionic gonadotropin, vaccines combining genes of gonadotropins linked to hepatitis B surface protein, monoclonal antibodies against human sperm

Considerable research has demonstrated that fertility can be controlled by antibodies and/or cells involved in immune functions, and much progress has been made in the development of immunologic approaches to contraception.[1, 2] A large body of clinical data has shown that infertility is often attributable to antibodies against reproductive tract antigens.[3] In addition, a number of investigators have experimentally induced infertility by immunizing animals against reproductive tract hormones[4-8] and gamete antigens.[9, 10]

Particularly promising are vaccines that are directed against human chorionic gonadotropin (hCG), four of which are undergoing phase I clinical trials. This article focuses on recent developments in this area and also briefly reviews current prospects for the development of the next generation of birth control vaccines.

Counter hCG vaccines

hCG was chosen as a target antigen for several reasons. It is synthesized and secreted in appreciable amounts as a result of conception, and it is a reliable index of pregnancy, provided that production of hCG by trophoblastic cancers and hydatidiform moles can be excluded.

Recent evidence indicates that hCG is synthesized by embryos fertilized in vitro before implantation.[11] It is believed that hCG is important in establishing early pregnancy and, indeed, antibodies that abrogate hCG terminate pregnancy.[6, 12, 13]

Different strategies have been used to develop vaccines against hCG. Talwar et al.[14] chose the entire β-subunit of hCG as the antigen, whereas Stevens et al.[15] used a carboxyl-terminal peptide of β-hCG. Although carboxyl-terminal peptides do not produce antibodies that cross react with human luteinizing hormone (LH), they are poor antigens that require the use of strong adjuvants. Antibodies generated by carboxyl-terminal peptides have a low bioneutralization capacity as compared with antibodies that are produced by immunization with the entire β-hCG subunit.[16] In addition, carboxyl-terminal peptides are not recognized by the corpus luteum or Leydig cell receptors.[17] Limited in vivo studies have been carried out with carboxyl-terminal peptides of varying lengths, with some investigators reporting efficacy and others finding none.[18, 19] In contrast, the contraceptive efficacy of immunization with the whole β-hCG subunit has been confirmed in baboons and marmosets by a number of investigators.[6, 8, 13]

β-hCG–tetanus toxoid vaccine. The first of these vaccines to be developed consisted of β-hCG linked to tetanus toxoid. It has been tested in 63 women in six centers located in five countries.* The vaccine was given in four injections at 2-week intervals. It produced a

*SPLPS, Sodium phthalyl lipopolysaccharide.

reversible antibody response against both hCG and tetanus,[14] which in good responders lasted for 300 to 500 days.[20,21] Immunization did not affect ovarian function; ovulation was maintained with progesterone produced normally in the luteal phase. No significant side effects were noted.[22-24] The main limitation of this vaccine was the large intersubject variability in antibody titers; subjects who had low titers of hCG antibodies were not protected against pregnancy.

Improved vaccine formulations. Further research has led to the development of two new vaccine formulations. One of them consists of β-hCG annealed to a heterospecies (ovine) α-subunit of LH and linked to two carriers, namely, tetanus toxoid and cholera toxin chain B. The rationale for this approach is as follows: Gonadotropic hormones contain two subunits. Maximal bioactivity of the hormone is achieved when the two subunits are associated, as this conformation is read optimally by the target tissue receptor. Dissociation of the subunits leads to a drastic conformational change and loss of bioactivity. α-hCG is not usable, because it would cross react with human thyroid-stimulating hormone (TSH) and human follicle-stimulating hormone (FSH). β-hCG, however, anneals readily to α-subunits of gonadotropins of other species, and the resulting conformation has a steroidogenic potential superior to that of hCG.[25] Ovine α-LH does not produce antibodies that cross react with human TSH or FSH. The annealed antigen, however, has a significantly higher immunogenicity in bonnet monkeys than does β-hCG–tetanus toxoid.[26]

The carrier in these specially structured vaccines contributes to immunogenicity and to immunoprophylactic benefit. Tetanus toxoid is a good carrier, but response to tetanus toxoid varies from recipient to recipient. The purpose of using two carriers, rather than one, is to evoke a response in those persons who are hyporesponders to tetanus toxoid. The gonadotropin subunits linked to cholera toxin chain B evoked a higher response in bonnet monkeys that had low titers after immunization with tetanus toxoid–based vaccine.[27] For this reason, these two carriers were chosen for use in the formulations that are now undergoing clinical trial.

The second improved vaccine formulation is a mixture of ovine β-LH and β-hCG, each linked to a carrier–tetanus toxoid and cholera toxin chain B. The mixture is eight to 13 times more immunogenic than β-hCG–tetanus toxoid in monkeys and rodents.[28] An additional benefit of including ovine β-LH is to introduce antibodies that cross react with human LH. Partial neutralization of the LH surge does not impair ovulation, but in monkeys it leads to a reduced rate of progesterone production in the corpus luteum and a shortening of the luteal phase by about 2 days.[29] Clinical cases of infertility have been recognized in women who have a slightly shortened luteal phase and deficient corpus luteum. Thus the mixed vaccine represents an attempt to simulate this condition by evoking antibodies that intercept fertility at two points in the reproductive chain of events.

The Population Council, New York, has carried out extensive safety studies involving 60 rhesus monkeys that were hyperimmunized with ovine β-LH in Freund's complete adjuvant. Careful toxicologic studies and histopathologic examinations over a 5- to 7-year period of observation did not show any pathologic conditions of the pituitary gland or the kidneys or other untoward side effects.[30]

Clinical trials. Four vaccines are currently undergoing phase I clinical trials (Table I), and the relative merits and limitations of each should become evident within the next 6 to 9 months.

The overall objective of the trials in India is to select the most immunogenic formulation of the vaccine. Study goals include determining whether 100 or 500 μg of gonadotropin(s) is the preferable dose for immunization; investigating the characteristics of the antibodies, including their bioneutralizing ability; observing the effects of the vaccines on reproductive and other body functions; and assessing the duration and reversibility of the antibody response.

The vaccines were released in May 1986 after due

clearance by the Drug Controller of India and Toxicology Review Panels of the Indian Council of Medical Research. Centers that conducted the trials also obtained clearances from their respective ethics committees. As of September 15, 1986, 76 subjects were enrolled in the study. Before immunization, baseline parameters were established for 2 months in each patient. By October, 21 women had received one injection of the vaccine, nine had received two, and one had completed the course of three injections at monthly intervals.

In all women, antibodies against hCG were measurable in the circulation. The subject who had received three injections had a titer of 78 ng of hCG binding capacity per milliliter. The affinity of the antibodies for hCG was 3.4 $nmol^{-1}$. The antibodies did not cross react with human FSH or TSH but cross reacted (13%) with human LH.

Thus far, no significant side effects have been reported. One subject who showed sensitivity to tetanus toxoid was excluded from the study. Three of the 21 subjects experienced overnight pyrexia after immunization, but this complaint was not related to the dose. Trials of a three-dose regimen of our first vaccine, the β-hCG–tetanus toxoid vaccine, are being resumed by the International Committee on Contraception Research of the Population Council in two Scandinavian centers.

Other fertility control vaccines at advanced stages of experimental development

Counter gonadotropin-releasing hormone (GnRH). The decapeptide hormone GnRH is common to both sexes, and immunization against it likewise controls fertility in both sexes. Although the efficacy of immunization against GnRH with Freund's complete adjuvant was shown more than a decade ago,[31] it has since become possible to create a vaccine that induces antibody titers high enough to be bioeffective in male[32] and female[33] animals with the use of appropriate adjuvants.

The GnRH vaccine may also have medical applications in precocious puberty and in such hormone-dependent cancers as carcinoma of the prostate and some breast neoplasms. However, because the vaccine reduces the levels of testosterone in immunized animals, its use as a male contraceptive is unlikely. Nevertheless, androgens are currently being tested that can meet the additional testicular demand in male animals that are rendered infertile by immunization against GnRH.

Counter FSH. Active and passive immunizations against FSH result in reduced sperm counts in monkeys.[4, 34] In rhesus monkeys, spermatogenesis was restored after 4½ years of active immunization, despite high circulating antibody levels.[34] Bonnet monkeys, however, remained infertile after active immunization against FSH.[4]

The next generation of birth control vaccines

The possibility of obtaining proteins by recombinant deoxyribonucleic acid methods has sparked active interest in sperm antigens. For example, active immunization against lactic dehydrogenase C_4, a tissue-specific sperm protein, significantly reduces fertility.[35] Many monoclonal antibodies have been developed against human sperm antigens; some of these antibodies demonstrate the presence of sperm-specific epitopes that may have important applications for fertility control and are likely to be developed as birth control vaccines.

The use of more than one antigen in vaccines will offer the advantage of intercepting fertility at more than one point. Polyvalent vaccines that consist of more than one reproductive tract antigen linked to more than one carrier are being developed and tested in our laboratory as well as in other laboratories. Also notable is the development of constructs of birth control vaccines at the deoxyribonucleic acid level. The β-hCG gene has been inserted along with the gene coding for hepatitis B surface protein.[36] Vaccinia has also been proposed as a possible vector for the next generation of live recombinant vaccines.[37]

Experiences with gossypol as a male pill

G. Z. Liu, M.D., K. C. Lyle, Ph.D., and J. Cao, M.D.
Beijing, China, and New York, New York

In 1981 to 1983 we performed a clinical study with gossypol involving 152 participants, and in 1983 to 1985 we conducted another study of 120 participants. The first study was aimed at confirming gossypol's antifertility efficacy and determining the existence of side effects. The objective of the latter study was to find out whether the addition of a potassium salt supplement or a potassium-sparing agent could alleviate the side effect of hypokalemia. In both studies, the participants took a gossypol pill, 20 mg/day for 60 to 75 days for loading, and 50 mg/wk for maintenance. All participants were followed up for a year. The antifertility efficacy was found to be more than 90%, and the chief side effect was lowered serum potassium. In our 1983 to 1985 study, we concluded that since neither potassium supplementation nor triamterene solved the problem, it is very likely that gossypol is a nephrotoxic agent. With 1 year of gossypol treatment, serum testosterone and serum luteinizing hormone showed no change, whereas serum follicle-stimulating hormone showed some elevation after 6 months. The Shanghai researchers found that in their gossypol users, plasma and urinary β_2-microglobulin levels were elevated to a certain extent. However, 25 subjects in our 1983 to 1985 study showed no appreciable change. Our volunteers had stopped taking gossypol for more than 1 year. In 1986 we started a third study, which was aimed at finding the lowest antifertility dose to minimize possible renal toxicity. (Am J Obstet Gynecol 1987;157:1079-82.)

Key words: Contraception, male, gossypol, irreversible aspermia, hypokalemia, nephrotoxicity

In the 1970s, a multicentered clinical study involving nearly 10,000 men showed that gossypol was an effective male antifertility agent. Its adverse effects were hypokalemia[1] and irreversible aspermia in a few cases. However, this study was not entirely satisfactory, chiefly because of a lack of uniformity in research protocols and inaccuracies in the basic data.

Enthusiasm for clinical gossypol studies gradually declined in the 1980s. The open door policy in China and practical attitude toward scientific research have brought about more careful study design and stricter verifications of data. The multicentered collaborative study of gossypol has given way to single-centered studies of this agent.

Recently, at the Peking Union Medical College Hospital we have performed two clinical gossypol studies, the purposes of which were to investigate the phenomenon of hypokalemia. Our 1981 to 1983 randomized controlled study involving 152 men attempted to clarify whether gossypol actually causes hypokalemia and if so how frequently.[2] The objective of our 1983 to 1985 study of 120 men was to determine whether hypokalemia is a direct effect of gossypol or a secondary manifestation of renal toxicity. In a third study, we investigated the lowest antifertility dose in the hope of minimizing toxicity.

From the Peking Union Medical College Hospital, and The Rockefeller Foundation.

Incidence of gossypol-induced hypokalemia

In the 1981 to 1983 study, the mean serum potassium level gradually declined during 1 year of gossypol treatment (Table I). The decline was obvious almost immediately after the initial loading phase. Later, serum potassium level continued to drop until leveling off toward the end of 1 year.

Clinical hypokalemia, however, occurred only occasionally. Only one of the 152 patients who participated in our 1981 to 1983 study experienced weakness of the neck muscle. This symptom developed in the third month of the maintenance phase when the patient's serum potassium level had fallen to 2.6 mEq/L. The patient's electrocardiographic changes were also typical. Five other patients in this study also had serum potassium levels below 3.0 mEq/L but did not develop any clinical symptom. After cessation of gossypol treatment, the decline in potassium levels did not persist. When gossypol was withdrawn after 1 year of gossypol treatment, serum potassium levels rose to a certain extent but did not return to the initial level.

One-year follow-up study of semen analysis showed a 49% incidence of irreversible aspermia.

Mechanism of gossypol-induced hypokalemia

In our second study, we investigated whether hypokalemia can be prevented by the addition of a potassium salt supplement or a potassium-sparing diuretic. Our goal was to test the hypothesis of those

scientists who consider hypokalemia to represent a direct effect of gossypol on serum potassium, which could be averted by the addition of potassium.[1]

Our 120 participants were divided into four groups. The first group took gossypol only, the second group took gossypol plus potassium chloride, 0.5 gm three times a day, the third group took gossypol plus triamterene, 50 mg/day, and the control group took nothing. In the first, second, and third groups, serum potassium declined to similar levels, although these decreases were less marked than those in our 1981 to 1983 study (Table II). This difference might be explained by the fact that the loading phase of our 1983 to 1985 study was 60 days, whereas that of our 1981 to 1983 study was 75 days.

One of the 120 patients developed clinical hypokalemia with lower limb paralysis 1 month after completion of 1 year of treatment. This patient's serum potassium level fell to 2.0 mEq/L and his electrocardiographic findings were typical. Although the patient responded very well to potassium supplementation, his serum potassium level 1½ years after cessation of gossypol treatment was still as low as 3.6 mEq/L compared with a pretreatment serum potassium level of 4.2 mEq/L.

On the basis of these results, we concluded that gossypol-induced hypokalemia should not be taken lightly as a direct effect of electrolyte imbalance. Rather, it should be viewed as caused by changes in an electrolyte-regulating organ, namely, the kidney.

Because to the best of our knowledge most kidney function tests were either too inconvenient or insensitive, we did not perform any such tests in either the 1981 to 1983 or the 1983 to 1985 study. However, in early 1986, we learned that the β_2-microglobulin test was convenient and sensitive and that our Shanghai colleagues had found abnormal test results in most of their volunteers.[3] We therefore called back some of the participants in our two studies. Our preliminary results of β_2-microglobulin testing in 25 patients who participated in the 1983 to 1985 study showed that renal function was not greatly impaired. The test was performed 1 year after the cessation of 1 year of gossypol treatment.

Prevention of gossypol-induced hypokalemia

Based on these considerations, we began a third study in 1986, with the goal of finding the lowest antifertility dose to minimize possible renal toxicity. Our low-dose study involved 39 participants. The first group of six participants took 15 mg/day for 60 days for loading and 45 mg weekly for maintenance. The second group of 13 participants took 10 mg/day for 60 days for loading and 30 mg weekly for maintenance. In addition, we had two control groups consisting of 10 participants each.

At the end of 60 days, the antifertility efficacy (sperm count <4 million/ml) was 67% in patients who received 15 mg loading doses but was only 23% in the 10 mg group (Table III). If antifertility efficacy is measured by the hamster egg penetration test, failure of penetration at the end of 60 days was 100% with the 15 mg regimen and 80% with the 10 mg regimen (Table III). No pregnancy occurred in the 15 mg group after 4 months without protection; one pregnancy took place in the 10 mg group after 1 month without protection.

Serum potassium level in the 15 mg group showed a tendency to drop after 60 days and decreased further after 120 days (Table IV). However, the difference was not statistically significant when compared with the control group.

Blood and urinary β_2-microglobulin levels in both the 15 mg and 10 mg groups showed no significant changes (Table V).

Table III. Fertility status after 60 days in the low-dose gossypol trial

Group	*No. of cases*	*Sperm count <4 million*	*%*	*No. of cases*	*Hamster egg penetration <10%*	*%*
15 mg	6	4	67	5	5	100
10 mg	13	3	23	10	8	8

Table IV. Serum potassium (mEq/L) in the low-dose gossypol trial

Group	*No. of cases*	*Admission*	*60 days*	*p*	*120 days*	*p*
15 mg	6	3.92 ± 0.26	3.73 ± 0.27	>0.05	3.45 ± 0.12	<0.01
Control	10	3.86 ± 0.26	3.78 ± 0.24	>0.05	3.52 ± 0.12	<0.01
p			>0.05		>0.05	
10 mg	13	3.82 ± 0.27	3.62 ± 0.28	>0.05		
Control	10	3.78 ± 0.24	3.52 ± 0.12	>0.05		
p			>0.05			

Table V. β_2-Microglobulin in the low-dose gossypol trial

Group	*No. of cases*	*Serum β_2-microglobulin*		*Urine β_2-microglobulin*		*p*
		Admission	*60 days*	*Admission*	*60 days*	
15 mg	6	3.03 ± 0.06	3.06 ± 0.05	2.04 ± 0.21	1.98 ± 0.30	>0.05
10 mg	13	3.08 ± 0.09	3.09 ± 0.06	1.94 ± 0.28	1.91 ± 0.25	>0.05
Control	10	3.09 ± 0.21	3.07 ± 0.19	2.27 ± 0.10	2.24 ± 0.16	>0.05
p			>0.05		>0.05	

Based on these data, the 15 mg regimen appears to be the appropriate way of providing dependable antifertility action while at the same time avoiding possible damage to the kidneys. With the 10 mg regimen, the loading and maintenance doses seem too low to ensure antifertility action. Since the sample size of our low-dose study is small, further study with more participants is warranted.

Melbourne, Victoria, and Prospect, New South Wales, Australia

It is now well accepted that a woman can conceive from an act of intercourse for a maximum of only about 7 days of her menstrual cycle. The reliability of natural family planning depends on identifying this window of fertility without ambiguity. Several symptomatic markers, cervical mucus and basal body temperature, have been used extensively and with considerable success in most women but failures occur. Ovarian and pituitary hormone production show characteristic patterns during the cycle. Urinary estrogen and pregnanediol measurements yield reliable information concerning the beginning, peak, and end of the fertile period, provided that the assays are accurate and performed on timed specimens of urine. We have developed such enzyme immunoassays for urinary estrogen and pregnanediol glucuronides that can be performed at home. In the early versions of the assays, enzyme reaction rates were measured by eye, but more recently, a simple photoelectronic rate meter has been used. The final problem to be solved is not technologic but whether women are sufficiently motivated to expend the same time and effort each day for 10 days a month, with less cost, on fertility awareness as they spend on making a cup of tea. (AM J OBSTET GYNECOL 1987;157:1082-9.)

Key words: Natural family planning, cervical mucus, basal body temperature, urinary estrogen and pregnanediol assays, enzyme immunoassays for urinary estrogen, pregnanediol glucuronides

Natural family planning is defined as voluntary avoidance of intercourse by a couple during the fertile phase of the menstrual cycle to avoid pregnancy.[1] Natural family planning thus involves a continual awareness of fertility status, including the day of ovulation. Therefore many regard the use of this awareness to expedite pregnancy as being part of natural family planning.

The earliest form of natural family planning was the rhythm or calendar method. The day of ovulation was considered to occur 14 ± 2 days before the next menstruation, and the period of possible fertility was calculated from this by allowing for the fertilizing life of the sperm and for normal variations in cycle length.[2] The rhythm method served a generation well; although many unplanned pregnancies occurred, the alternatives available at that time also had high failure rates.

The situation changed dramatically with the introduction of hormonal contraception after the pioneering work of Pincus and Rock and several pharmaceutical firms. The virtual 100% effectiveness of the hormonal pill raised the population's expectations for family planning and also played a large part in the emancipation of women, enabling them to become as reliable wage earners as men.

In comparison, the rhythm method seemed too unreliable. At that time, many scientists doubted whether periods of infertility actually occurred during the human cycle. Indeed, many believed that ovulation could occur more than once and could be induced by copulation. The enormous increase in our knowledge of human reproduction since then has shown that these objections are incorrect and that the concept behind natural family planning is theoretically sound, namely, that there are definite periods of fertility and infertility during the menstrual cycle. Fig. 1 shows that the chances of conception from an act of intercourse are very low 6 days before ovulation, increase to a maximum during the day before ovulation, and fall to zero within 24 hours after ovulation.[3]

The scientific challenge then is to devise methods for identifying these periods of fertility and infertility with absolute certainty so that couples who use natural family planning have the same reliability as those using other modern methods of family planning. The main difficulty in natural family planning for motivated couples is not the periodic abstinence required, which may in fact enrich the union. Rather, it is the uncertainty in defining the fertile phase accurately, the excessive abstinence that is therefore required for maintaining adequate safety margins, and the loss of confidence resulting from unexplained pregnancies.

Symptoms

Fig. 2 shows the various indexes that have been applied to natural family planning. The rhythm calcula-

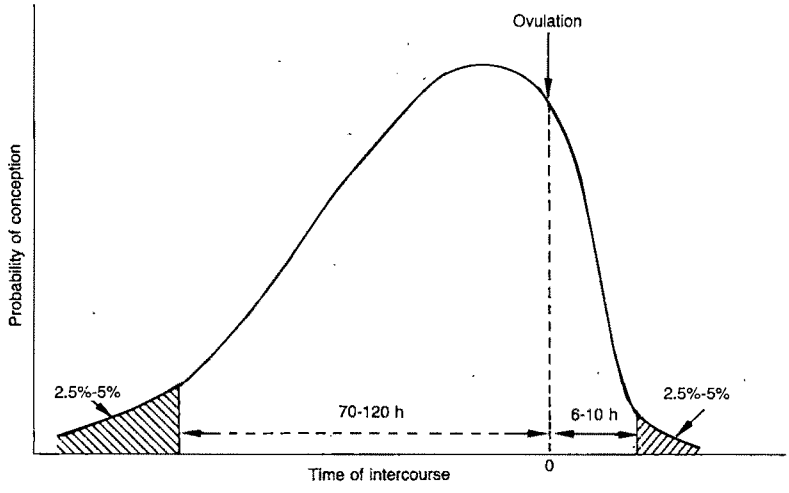

Fig. 1. Probability of conception *v*, the time of intercourse relative to ovulation in the human. (Reproduced with permission from Austin CR. Sperm fertility, viability and persistence in the female tract. J Reprod Fertil [Suppl] 1975;22:75-89.)

tions provide the background information on when ovulation can be expected in regular cycles.

Basal body temperature. The basal body temperature shows a characteristic rise of approximately 0.3° C after ovulation, which is caused by the rise of progesterone. The basal body temperature, which is measured orally or vaginally, was the standard method in scientific circles for timing ovulation before the advent of hormone assays.

The basal body temperature has been used extensively for natural family planning. In this context, it can be concluded that the fertile phase has ended and the late safe days have begun when the basal body temperature has been elevated for three consecutive days. The 3-day rule allows for possible errors. The accuracy of the measurement has been increased by the use of electronic thermometers, but even so the error of the method is considerable.[4] Moreover, in natural family planning, basal body temperature has little value in determining infertility in abnormal cycles, which are common in times of stress, during breast-feeding, and in the climacteric. Marshall[5] studied 4749 regular cycles in 321 couples who restricted intercourse to the late safe days (last third of the cycle), as determined by basal body temperature, and found a failure rate of 6.6 pregnancies per 100 woman-years.

Cervical mucus. The amount and quality of the mucus produced at the cervix and the appearance of the cervix itself undergo marked changes throughout the ovulatory cycle. Shettles[6] predicted the use of these symptoms for natural family planning, but they were not widely used until Billings[7] showed that women could readily identify these changes simply by noting sensations in the vulval area. Furthermore, Billings showed that the last day of clear, slippery, "fertile-type" mucus resembling raw egg white before the change back to minimal, thick mucus was closely associated with ovulation and was the day of maximum fertility. This was defined as the "peak" day.[7] These observations were tested by extensive laboratory hormone analyses, which showed that the beginning of the mucus symptom coincided with the beginning of estrogen production by the ovaries (on average, 6 days before ovulation), that the symptoms reached a maximum on the day of the preovulatory estrogen peak, that the peak day occurred within ± 1 day of ovulation in 78% of cycles (n = 179), and that the rapid return to "infertile-type" mucus was caused by the rapid postovulatory rise in progesterone.[8-10] Rules were formulated to apply these findings to the identification of both the early and late safe days of the cycle for natural family planning in the complete range of normal and abnormal cycles. This method of natural family planning, which depends solely on the mucus symptoms, is known as the ovulation method (Billings) and is used worldwide.

To use the ovulation method, couples require adequate training. The World Health Organization has performed a prospective trial of this method in five countries (New Zealand, Ireland, the Philippines, India, and El Salvador) to assess its acceptability and effectiveness. The teaching phase involved 884 couples for three cycles each, and the application phase included 725 couples for a total of 7514 cycles. Ninety-three percent of the women could be taught to recognize and record their symptoms within three cycles; the average number of days per month required for abstinence was 17. The discontinuation rate after 13 cycles was 36%, 20% of which was because of pregnancy. The pregnancy rates per 100 woman-years were 15% as a result of conscious departure from the rules,

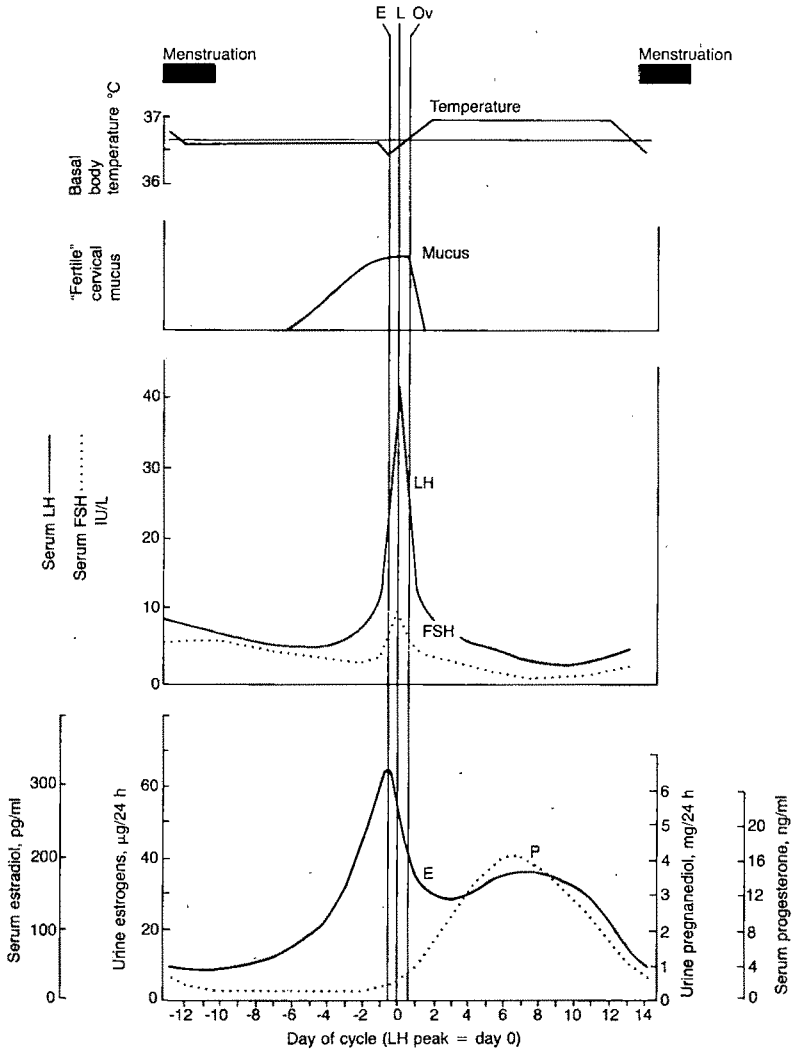

Fig. 2. Mean values for serum luteinizing hormone *(LH)*, follicle-stimulating hormone *(FSH)*, estradiol, progesterone, and urinary estrogens, and pregnanediol throughout the menstrual cycle. Basal body temperatures and times of mucus production and menstruation are shown. The *vertical lines* represent the times of preovulatory estrogen peak *(E)*, LH peak *(L)*, and ovulation *(Ov)*.

3.5% as a result of inaccurate application of instructions, and 3.0% as a result of actual method failure. The rate of pregnancy resulting from method failure varied from 9.4 per 100 woman-years in New Zealand to 5.1 in Ireland, to 1.1 in the Philippines, to 0 in India and El Salvador.[11] The results provided satisfaction for all parties, whatever their point of view.

The outcome of the World Health Organization trial highlights the difficulties involved in comparing natural family planning with other methods of family planning. Natural family planning provides couples with information and not contraception. The contraceptive efficacy of the method depends on how the couples apply the information and on whether they change their minds at any time.

The symptothermal variants of the ovulation method add basal body temperature and the rhythm calculations. However, it is unlikely that further major breakthroughs in natural family planning will result from refinements of the symptoms alone.

Hormone assays

We have investigated the use of home hormone analyses for natural family planning. During the validation of the ovulation method, we found that the women used the results of our urinary estrogen and pregnanediol assays for natural family planning in preference to using their symptoms. These assays depend on spectrophotofluorimetry and gas-liquid chromatography and are still our reference methods.[12, 13] We therefore embarked on the development of simpler analytic methods, with the aim of using the urinary estrogen assay

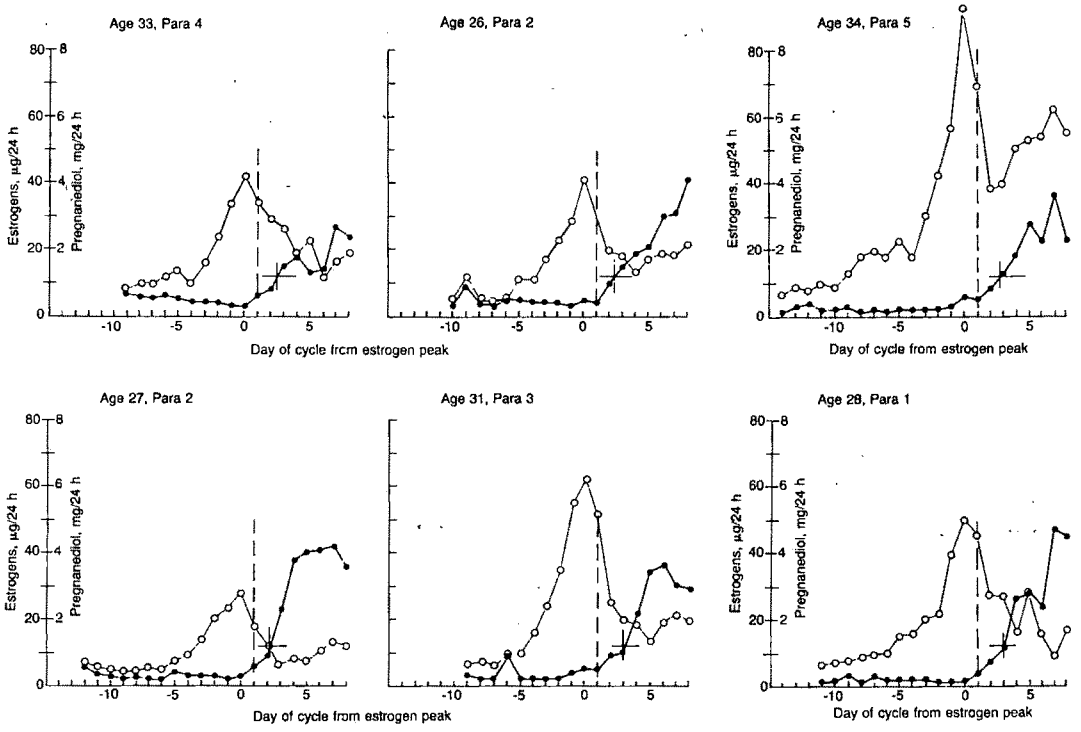

Fig. 3. Six individual cycles showing urinary estrogen and pregnanediol values. Day of the preovulatory estrogen peak = day 0. The *vertical dotted line* is the estimated day of ovulation. The point at which the pregnanediol values reached 1.2 mg/24 hr is marked with a cross.

to determine the beginning of the fertile phase and the pregnanediol assay to signal its end (Figs. 1 and 2). The base data for this development are shown in Fig. 3 for six cycles. Many more examples could be shown to illustrate the points.

The development of suitable home assays was a formidable task for several reasons: (1) These assays must be simple and rapid enough to be performed at home; (2) they must be as reliable and accurate as the best laboratory assays available, since errors will lead to unplanned pregnancies (this is a far more exacting requirement than that needed for the assessment of infertile patients); (3) timed specimens of urine collected overnight, or at least for a 3-hour period, are necessary to achieve the required daily accuracy independent of fluid intake; (4) no noxious chemicals can be used; and (5) the assays must be inexpensive (less than 10 cents each) and easily produced in large numbers.

All these requirements have largely been achieved. We used the system of homogeneous enzyme immunoassay using lysozyme conjugates[14] and measured the urinary estrogen and progesterone metabolites as their glucuronides.[15] We developed methods for both laboratory (wet chemistry) and home use, in which the antisera, conjugates, and substrate are applied to the walls of glass tubes (eye test) or plastic colorimeter cells (photometer test). In the home version, all that is necessary is the accurate addition of urine (diluted to 125 ml/hr with tap water) and water and final mixing. The enzyme reaction is measured by the change in transmission over time either by eye or by a simple regulated temperature photometer with an internal timer.

Measurement of urinary pregnanediol glucuronide

The eye test uses a standard tube set to have an enzyme rate equivalent to 5.3 µmol pregnanediol/24 hr (1.2 mg/24 hr); this controls for time and temperature. The reaction takes about 10 minutes, depending on the room temperature, and the results of the test are recorded as very negative, negative, plus-minus, positive, or very positive, relative to the clearing rate of the standard. This test has been used in the home by 32 women who were selected because they had difficulty in recognizing their symptoms or needed absolute contraception for medical reasons. A total of 184 cycles was studied. The tests were performed by the women or their husbands at home, and the results were checked in the laboratory by both the eye test and quantitative assay.

Fig. 4 summarizes the results obtained with the eye test performed in the laboratory compared with the true values obtained by quantitative assay. Plus-minus values, which should have been 5.2 µmol/24 hr,

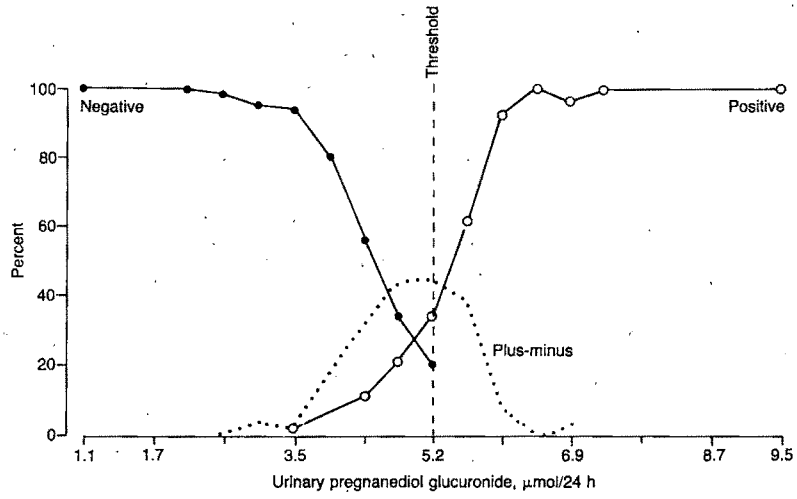

Fig. 4. Percentage of positive, negative, and plus-minus results obtained at each pregnanediol glucuronide level when using the eye test in the laboratory (184 cycles). (Reproduced from Bachelor of Medical Science thesis, Monash University, Melbourne, Australia, 1986 with permission of the author, B. Conway.)

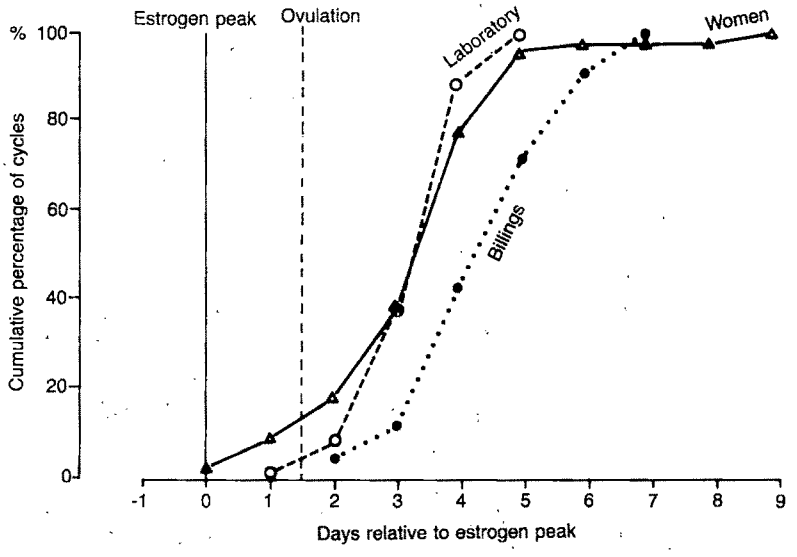

Fig. 5. Cumulative percentage of cycles shown in terms of the day when the pregnanediol eye test (performed at home and in the laboratory) and the mucus symptoms allowed resumption of intercourse (44 cycles). (Reproduced from Bachelor of Medical Science thesis, Monash University, Melbourne, Australia, 1986 with permission of the author, B. Conway.)

were obtained over the actual range of 3.5 to 6.5 μmol/24 hr. This illustrates the remarkable ability of the eye to distinguish between relatively small changes in pregnanediol concentration over the crucial range of interest. As might be expected, the women at home did not do as well, but the results yielded important information on how lay persons cope with scientific analyses and interpret the results. The rule was formulated that a plus-minus value followed by a clear positive or a positive value followed by a more positive value should be obtained before the resumption of intercourse. The results shown in Fig. 5 were obtained. The women using the eye test at home gained one more safe day than they would have with the mucus symptoms method, and none conceived with this rule.

The meter version of the home pregnanediol test has been tested only in the laboratory because of the shortage of photometers. The wet chemistry version of this assay has been compared with the reference laboratory method (x) by means of gas-liquid chromatography and corrected to 100% recovery. The correlation coefficient r was 0.96, and the regression line was Y = 1.13x +

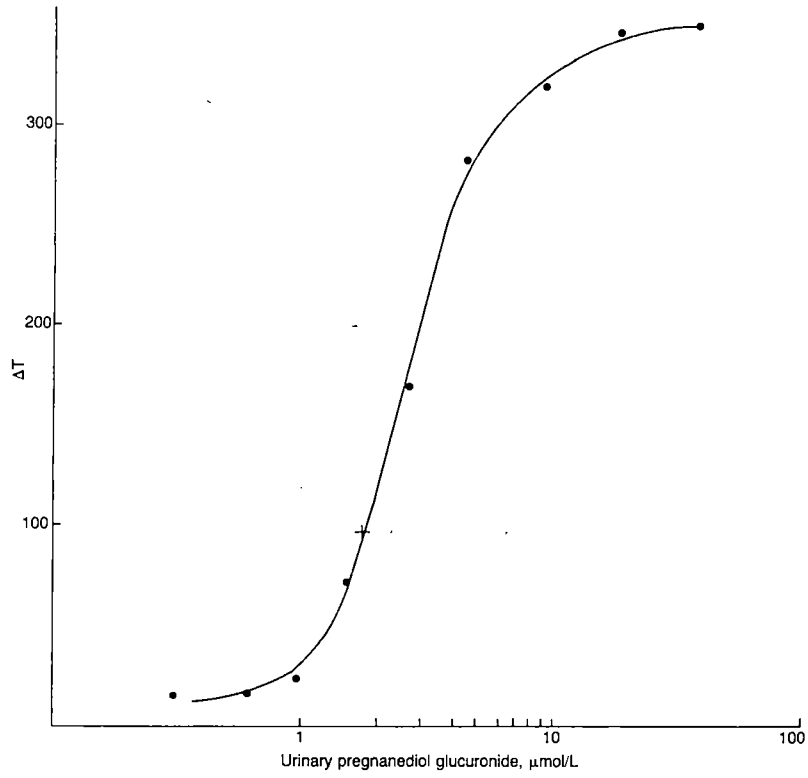

Fig. 6. Standard curve for urinary pregnanediol glucuronide (enzyme immunoassay).

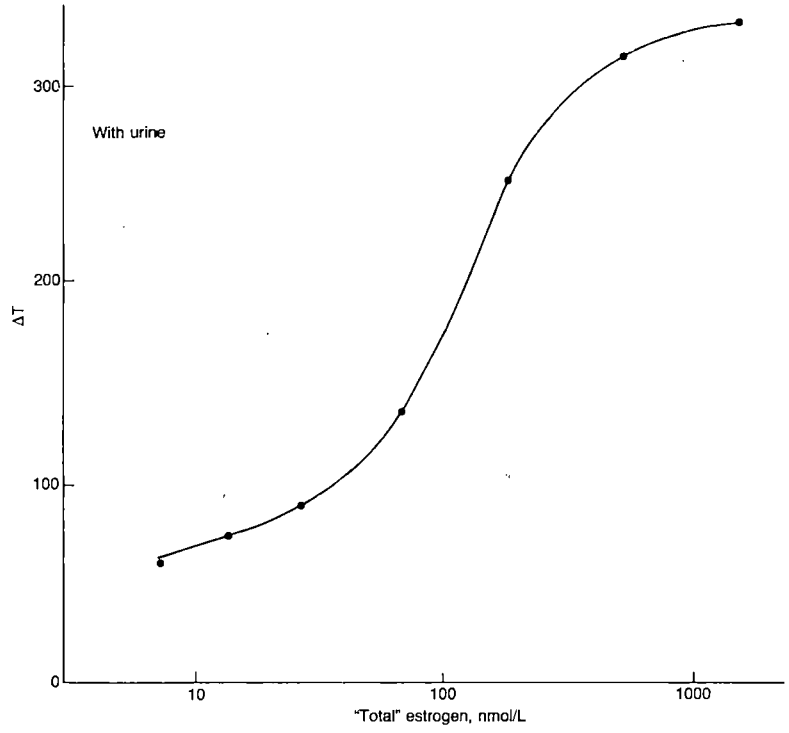

Fig. 7. Standard curve for urinary estrogen glucuronides (enzyme immunoassay).

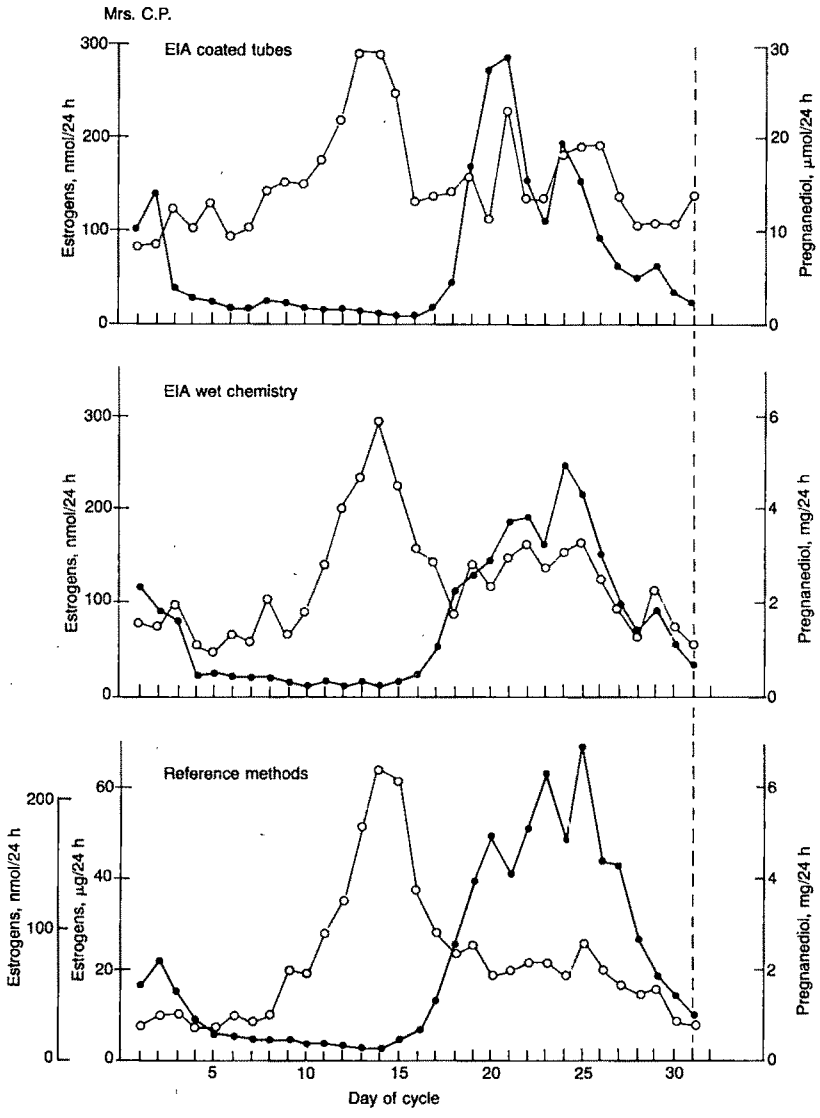

Fig. 8. Preliminary results from a normal cycle showing urinary estrogens measured by spectrophotofluorimetry (reference method) and enzyme immunoassay and urinary pregnanediol measured by gas-liquid chromatography (reference method) and enzyme immunoassay (both wet chemistry and coated tubes). Quantitative differences between methods are mainly due to whether allowance has been made for losses occurring in the reference (extraction) methods. The estrogen enzyme immunoassay shows a urine bias that results in higher baseline values than those given by the reference method.

0.01 µmol/24 hr (n = 65). The slope 1.13x is consistent with the known presence of irremovable water of crystalization in the pregnanediol glucuronide used for standards. The enzyme immunoassay for pregnanediol glucuronide has been extensively validated, and as a 30-second wet chemistry procedure, has been used routinely for 3 years in our laboratory. A standard curve for urinary pregnanediol glucuronide is shown in Fig. 6. The reliability criteria of the home meter assay, which uses a reaction time of 5 minutes, are currently being evaluated. It gives the same results as the wet chemistry: Y = 0.99x − 0.07 µmol/24 hr (n = 22); the precision depends on the accuracy of adding the components to the coated tubes and is continually being improved.

Measurement of urinary estrogen glucuronides

The development of an enzyme immunoassay for estrogen has been more difficult because the amounts being measured are much smaller. Nevertheless, a working assay is now being evaluated. The assay requires a photometer, and the reaction time is 20 minutes. It is available as wet chemistry for laboratory use and coated tubes for home use. The assay measures a

mixture of estrone-glucuronide, estriol-3-glucuronide, and estriol-16-glucuronide.

A standard curve for urinary estrogen glucuronides is shown in Fig. 7. Application to a complete menstrual cycle is shown in Fig. 8, together with the results obtained by the reference estrogen method and the pregnanediol methods of enzyme immunoassay and gas-liquid chromatography. The early estrogen rise and the preovulatory estrogen peak are readily identified. When the first production run of photometers is finished shortly, these methods will be completely evaluated for home, medical center, and laboratory use and will then be made available for distribution.

Discussion

In summary, we can state that women can collect timed specimens of urine and perform pregnanediol analyses at home with competence. The corresponding estrogen assay is ready for similar testing. Application of these analyses to large populations of women practicing natural family planning will greatly increase our knowledge of human reproduction in all its aspects. Their full value in the teaching and practice of natural family planning and in the assessment of infertility has yet to be determined. Furthermore, having unambiguous identification of the day of ovulation in unplanned pregnancies will make it possible to determine exactly what went wrong. This will surely help increase the effectiveness of natural family planning in the same way that in-flight black box recorders have increased the safety of air travel.

These methods may seem to be too complicated to be performed and interpreted by most women at home. However, they involve less labor and cost than does making a cup of tea. In interpreting these assays, the patterns obtained are as important as the absolute amounts. A woman starts early in her cycle by measuring urinary estrogens. She will first see baseline values, followed by a rise, which indicates the beginning of fertility. When this rise is clearly established or a fall occurs, she changes to measuring pregnanediol. When postovulatory pregnanediol values are clearly reached (5.2 μmol/24 hr), she knows that the late safe days have started and that no further testing is required for that cycle. This represents a total of approximately 12 days of testing. It remains to be seen whether widespread education will lead to a general application of this aid to natural family planning.

A new delivery system for contraceptive steroids

Sheldon Segal, Ph.D.
New York, New York

Long-acting forms of contraception that take advantage of the tissue compatibility of silicone rubber, a polymer of dimethylsiloxane, have been developed. The most advanced type of subdermal contraceptive capsule contains about 36 to 40 mg of levonorgestrel and is 30 mm in length and 2.4 mm in diameter (Norplant). The set of six implants is placed under the skin of the upper arm with a 10-gauge trocar with the use of a local anesthetic. The basis for the antifertility effect of these implants is continuous, low-dose progestogen therapy without the use of estrogen. The capsules release a total of approximately 39 μg of levonorgestrel each day. The blood progestogen level achieved through this microabsorption delivery system is 0.25 to 0.3 ng/ml. There is a sufficient supply of steroid in the capsules to maintain this blood progestogen level for 5 to 6 years. Since the capsules can be removed at any time, this contraceptive method is voluntarily reversible. The effectiveness of these subdermal implants has been evaluated in long-term studies that have progressed for well over 5 years. Therefore one clinic visit eliminates nearly 2000 days of concern over having to remember to take a pill on schedule. There has been sufficient experience to assure that fertility recurs promptly after removal of the subdermal implants. (Am J Obstet Gynecol 1987;157:1090-2.)

Key words: Contraception, long-acting subdermal implants, levonorgestrel

Many new delivery systems are under investigation in the field of contraception. Among these are systems that use silicone rubber, a polymer of dimethylsiloxane, as a carrier for the slow release of contraceptive progestogen.

Evolution of subdermal contraceptive implants

The development of a long-acting form of contraception that takes advantage of the tissue compatibility of silicone rubber began in our laboratories some 20 years ago with the demonstration that many steroid substances can be released from silicone rubber at a slow and steady rate. Lipophilic compounds, such as steroids, are soluble in and pass through a solid matrix of polydimethylsiloxane. Thus a supply of crystalline steroid stored within a silicone rubber capsule will pass through the polymer wall at a controlled rate. The steroid can also be released from a solid rod composed of a mixture of liquid polymer and crystalline steroid, which is homogenized and then prompted to solidify by adding an appropriate catalyst. Silicone rubber was also deemed suitable as a basis for a contraceptive modality because of its record of medical safety. Silicone rubber tubing has been used for subdermal hydrocephalus drains, and a medical-grade preparation of the polymer is used in various reconstructive or cosmetic surgical procedures.

By 1968 the first clinical trials had begun, and 3 years later, a series of studies were undertaken to choose the best progestogen candidate for use in a long-acting, low-dose, continuous administration contraceptive. Levonorgestrel was selected as the compound of choice for the first subdermal contraceptive implant system because it is released at the extremely slow rate of about 10% of the original load per annum. This means that it would take about 5 years for 50% of the original dose of levonorgestrel to be released, which portended a very long duration of contraceptive efficacy.

The subdermal contraceptive system of Norplant has

Table I. Plasma levonorgestrel levels with Norplant

been developed as a hollow capsule 30 mm in length and 2.4 mm in diameter filled with about 36 to 40 mg of crystalline levonorgestrel. The capsules are placed under the skin of the upper arm with a 10-gauge trocar with the use of a local anesthetic. The steroid is released at a slow, controlled rate of about 6 μg per capsule per day. Therefore a set of six implants results in a release rate of about 36 to 40 μg/day, which is sufficient to achieve an antifertility effect. A second system, Norplant-2, has also been developed and consists of a solid rod of homogenized 50% silicone rubber–50% steroid mixture covered with ultrathin silicone rubber tubing to hold the entire rod in place as steroid dissolution proceeds.

Efficacy and safety

The effectiveness of Norplant has been evaluated in long-term studies that have progressed for well over 5 years. Table I shows that plasma levonorgestrel remains at a relatively constant level approximating 0.3 ng/ml over a 5-year period, declining just slightly in the fifth year. Plasma levonorgestrel levels high enough to protect against pregnancy are maintained 2 to 3 years beyond the recommended 5-year period of effectiveness. This may be potentially important should the user delay returning for a replacement set of implants.

In one 5-year study, only 11 pregnancies occurred in 2380 woman-years of use, which translates into a pregnancy rate well under 1 pregnancy per 100 woman-years of use (Table II). Life-table analysis of another 5-year study involving nearly 1000 women indicates that the level of protection against pregnancy year by year approaches the effectiveness of surgical contraception. In this clinical trial, the 50% discontinuation of use rate was reached at about 3 years (Table III).

The main reason for discontinuation of Norplant is menstrual problems, most commonly frequent irregular bleeding (Table IV). About 5% of women discontinue the method for this reason during the first year of use, an additional 1.5% do so during the second year, and an additional 1% or less during the third year. The total discontinuation rate from bleeding-related problems after 3 years is 15.1% (Table IV). Amenorrhea is rarely a cause for discontinuation.

Extensive safety studies carried out with Norplant indicate no unfavorable changes in liver function, lipid metabolism, or blood pressure, no increase in the risk

of ectopic pregnancy, and no increase in total menstrual blood loss. In fact, Norplant tends to increase hemoglobin levels in women who had low levels before using the implants.

Since the implants can be removed at any time, this contraceptive method is voluntarily reversible, and there has been sufficient experience to ensure that fertility recurs promptly after discontinuation. According to one study of women who discontinued the use of either Norplant or an intrauterine device because they wished to become pregnant, approximately three quarters of women in both groups became pregnant within 1 year (Table V).

Much of the data discussed here comes from studies of the 6-capsule Norplant system. However, clinical trials of the Norplant-2 system show essentially the same level of performance over a 3-year period of observation.

Norplant has been approved for general use in Finland, Sweden, Thailand, Indonesia, and the Dominican Republic and is being tested in 31 additional countries, including the United States. First-year results from field studies in some countries confirm the very high level of effectiveness that had been observed in the clinical trials (Table VI). The continuation rates are even higher than those reported in the clinical trials and range around 90% after the first year of use. This generally favorable experience has continued in years 2, 3, and even 4 in some of these field trials.

In summary, the high efficacy of Norplant makes this contraceptive method an important reversible alternative to sterilization. It affords long-acting protection, which means that one visit to the clinic can replace virtually thousands of days of pill taking. Norplant can be used for birth spacing because the implants can be removed at any time and fertility restored without impairment. It is also a suitable option for immediate postabortal use and when intrauterine devices or estrogens are contraindicated. New routes of administration should thus prove to be an important adjunct to existing modalities for effective and reversible contraception.

on oral contraception:

"The multiphasics contain a low dose of progestin without having an increased incidence of breakthrough bleeding."[3]

"If changes in HDL and HDL_2 levels are to be avoided... the preferred progestin is the estrane norethindrone and not the gonane norgestrel...."[4]

Low BTB with Tri-Norinyl

- Extra midcycle protection that's unique among multiphasics
- Low BTB rates—equivalent to a fixed low-dose OC[2]

Low Impact with Tri-Norinyl

- Minimal lipid and cholesterol impact[4]
- Low incidence of nuisance side effects[2]

TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

THE LOWEST-DOSE MULTIPHASIC OC WITH NORETHINDRONE

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see brief summary of prescribing information on next page.

TRI - NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg; 7 inert tablets)

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM.* Because studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.

MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to nonsmoking users, and a 10-12-fold increased risk compared to nonsmoking nonusers. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OCs. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34 – 5/100,000; ages 35-44 – 33/100,000; ages 45-49 – 140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34 – 1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over – 1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only/smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS – RISK ASSOCIATED WITH USE OF OCs

Age	Below 30	30-39	40+
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A – Use associated with very high risk.
B – Use associated with high risk.
C – Use associated with moderate risk.
D – Use associated with low risk.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (3.1-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer to OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer, and other studies suggested an increased risk of breast cancer with long-term OC use before age 25. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. Two other studies suggested an increasing incidence of cervical neoplasms with longer duration of OC use. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. (See also Warnings, 4. *Liver Tumors.*) 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use; risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. Cases of hepatocellular carcinoma have been reported in long-term users of OCs.[105-107] An epidemiological study suggested a 4-fold increase in relative risk for hepatocellular carcinoma in OC users for 8 years or more, which increased to 7 in women with markers of hepatitis B. A second study suggested a risk of about 20 for use in excess of 5 years. 5. *Use in or Immediately Preceding Pregnancy; Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones – estrogenic and progestational agents – during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero.* These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) than among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible pregnancy at the first missed period (or 45 days from the last menstrual period if progestogen-only OCs are used) and discontinue OC use until pregnancy has been ruled out. For any patient who has missed two consecutive periods, rule out pregnancy before continuing the OC. If pregnancy is confirmed, tell the patient about potential risks to the fetus and discuss advisability of continuing the pregnancy. Women who discontinue OCs to become pregnant should use an alternate form of contraception for a period of time before attempting to conceive. A 3-month period is supported by a study suggesting increased frequency of neural tube defects in women impregnated during the first 3 months after cessation of OC use. Do not use progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladder Disease:* Studies report increased risk of gall bladder disease in OC or estrogen users. In one study, an increased risk appeared after 2 years of use and doubled after 4-5 years. In another study, an increased risk was apparent between 6 and 12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease in glucose tolerance has been observed in a significant percentage of patients on OCs, prediabetic and diabetic OC users should be carefully observed. An increase in triglycerides and total phospholipids has been observed in OC users but its clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with OC use. Hypertension may occur within a few months of beginning OCs. In the first year of use, incidence of hypertension may be no higher in OC users than in nonusers. Incidence in users increases with exposure and in the fifth year of use is 2.5-3 times that in the first year. Age is strongly correlated with hypertension in OC users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, history of toxemia or elevated blood pressure during pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevated blood pressure when given OCs and should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, closely watch elevations, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after OC discontinuation. 9. *Headache:* Discontinue OC and evaluate the cause of onset or exacerbation of migraine or development of a new pattern of headache which is recurrent, persistent, or severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses often make users discontinue OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, consider nonfunctional causes. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, use acequate diagnostic measures to rule out pregnancy or malignancy. If pathology has been excluded, time or another formulation may solve the problem. While potentially useful in minimizing menstrual irregularity, change to an OC with a higher estrogen content only if necessary since this may increase the risk of thromboembolic disease. Women with a history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may tend to remain anovulatory or to become amenorrheic after OC discontinuation. Women with these preexisting problems should be advised of this and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased incidence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing OCs in comparison with other contraceptive methods, which appears to be independent of duration of use. While impairment diminishes with time, there is an appreciable difference in the results in nulliparous women for OC and other groups 30 months after discontinuation of birth control. For parous women the difference is not apparent 30 months after cessation of contraception. One study suggests that the incidence of *Chlamydia trachomatis* infection, the leading cause of nongonococcal PI.D., is increased by OCs. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in OC failure. In progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in nonusers, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* OCs in the postpartum period may interfere with lactation by decreasing quantity and quality of breast milk. A small fraction of OC hormonal agents has been identified in milk of mothers receiving OCs. Effects, if any, on the breast-fed child have not been determined. If feasible, defer OC use until the infant has been weaned. **Precautions** *GENERAL* 1. Take a complete medical and family history before starting OCs. Pretreatment and periodic physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant lab tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may enlarge. 3. Observe patients with a history of psychic depression and discontinue OCs if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the OC and use an alternate method of contraception to determine whether the symptom is drug related. 4. OCs may cause some fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions that might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while using OCs. Discontinue OC if jaundice develops. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism that may result in a relative pyridoxine deficiency. The clinical significance is unknown. 8. Serum folate levels may be depressed by OC use. Since the pregnant woman is predisposed to folate deficiency and incidence of folate deficiency increases with increasing gestation, if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and related complications. 9. Advise the pathologist of OC use when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing OCs. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. f. Increased phospholipids and triglycerides. g. Temporarily decreased glucose tolerance. 11. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist and temporary or permanent cessation of wear considered. DRUG INTERACTIONS. OCs may be less effective and there may be increased breakthrough bleeding from interactions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers, antimigraine preparations, antihistamines, and griseofulvin. OCs may alter effectiveness of such other drugs as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic preparations, theophylline, and beta blockers. Toxic liver effects have been reported with a combination of an OC and cyclosporin A. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings. **Adverse Reactions** An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, Budd-Chiari syndrome, Raynaud's disease, arterial thromboembolism. The following adverse reactions have been reported in OC users and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, changes in corneal curvature (steepening), change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution of lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors, chilblains. The following adverse reactions have been reported in OC users and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosclerosis (hemolytic uremic syndrome), malignant hypertension, acute renal failure, premature supraventricular contractions. **Information for the Patient** (See Patient Package Insert).

A Standard in Progesterone Therapy

Provera® 10 MG TABLETS
(medroxyprogesterone acetate)

WARNING

THE USE OF PROGESTATIONAL AGENTS DURING THE FIRST FOUR MONTHS OF PREGNANCY IS NOT RECOMMENDED.

Progestational agents have been used beginning with the first trimester of pregnancy in an attempt to prevent habitual abortion or treat threatened abortion. There is no adequate evidence that such use is effective and there is evidence of potential harm to the fetus when such drugs are given during the first four months of pregnancy. Furthermore, in the vast majority of women, the cause of abortion is a defective ovum, which progestational agents could not be expected to influence. In addition, the use of progestational agents, with their uterine-relaxant properties, in patients with fertilized defective ova may cause a delay in spontaneous abortion. Therefore, the use of such drugs during the first four months of pregnancy is not recommended.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies including congenital heart defects and limb reduction defects. One study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000.

If the patient is exposed to PROVERA Tablets (medroxyprogesterone acetate) during the first four months of pregnancy or if she becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus.

INDICATIONS: Secondary amenorrhea; abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

CONTRAINDICATIONS: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate. As a diagnostic test to pregnancy.

WARNINGS: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature; whereas the nodules in the drug treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, onset of proptosis, diplopia, or migraine. If papilledema or retinal vascular lesions occur, withdraw medication. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended (see Warning box). **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation, and it was not enhanced by long-continued administration.

PRECAUTIONS: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause fluid retention; therefore, carefully observe patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In irregular bleeding per vaginum, bear in mind nonfunctional causes and perform adequate diagnostic measures. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combinations; therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders. (See Patient Information for complete prescribing information.)

ADVERSE REACTIONS: Pregnancy: (see Warning box); **Breast:** rare reports of breast tenderness or galactorrhea; **Skin:** sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; **Thromboembolic Phenomena** including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; edema; change in weight; changes in cervical erosion and secretions; cholestatic jaundice; rash (allergic) with and without pruritus; mental depression; anaphylaxis and anaphylactoid reactions; pyrexia; insomnia; nausea and somnolence.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed in patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome; changes in libido; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; fatigue; backache; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching.Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein retention and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X); metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values).

Caution: Federal law prohibits dispensing without prescription.

Satisfaction realized:

87% patient continuation rate† with Ortho ALL-FLEX* Arcing Spring Diaphragm.

Easy for patient to insert—
the Ortho ALL-FLEX* Diaphragm folds easily.

Easy for patient to correctly position in vagina—
the Ortho ALL-FLEX* Diaphragm can be compressed at any two opposing points around the rim.

Easy to use with **GYNOL II* (2% nonoxynol-9) Contraceptive Jelly**—
greaseless, odorless spermicide.

Easy to clean—one-step molding process eliminates gap between spring and dome so jelly or secretions can't accumulate.

Ortho ALL-FLEX*
D I A P H R A G M

†Percentage of patients continuing the method for 12 consecutive months.

Consult the revised patient brochure for new information on Toxic Shock Syndrome (TSS) and wearing time.

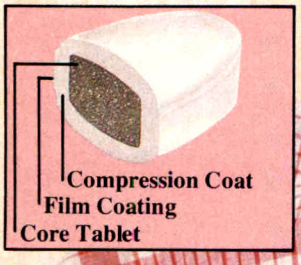
Natalins® Rx

Multivitamin and Multimineral Supplement with 1 mg Folic Acid

The Only Prenatal Vitamin with No Artificial Color or Flavor from Synthetic Sources

The Recipe for Prenatal Good Health



Good things are made from the finest ingredients. And the ingredients for maintaining good prenatal health make NATALINS Rx a standout . . . inside and out.

NATALINS Rx is the first and only prescription vitamin and mineral supplement with "natural" color and flavor. It contains all the mandatory and optional vitamins and minerals, plus copper and zinc, both important in the metabolic process.

Unique NATALINS Rx Construction Aids Compliance and Maintenance of Good Health

An elliptical tablet shape and a cellulosic film coating that becomes slippery when wet allows for easier, more comfortable swallowing—aiding patient compliance. Beneath the special coating, a central "core tablet" stores iron for delayed release, reducing the risk of stomach upset.

NATALINS Rx . . . the "Natural" Choice for Prenatal Good Health.

NATALINS® Rx

Ingredients	Natalins Rx	
VITAMINS	**Units**	**% RDA**
Vitamin A, IU	8000	100
Vitamin D, IU	400	100
Vitamin E, IU	30	100
Vitamin C, mg	90	150

Copper, mg	2	100
Zinc, mg	15	100
Artificial color		none
Artificial flavor		none

Natalins Rx is a multivitamin, multimineral supplement for pregnant or lactating women. Daily dose: 1 tablet or as prescribed.
Contraindications: Natalins Rx should not be prescribed in patients with hemochromatosis or patients with Wilson's disease.
Caution: Pernicious anemia should be excluded before using this product. In patients with kidney stones, the calcium content of Natalins Rx tablets should be considered before prescribing.
Supplied: Bottles of 100 and 1,000.

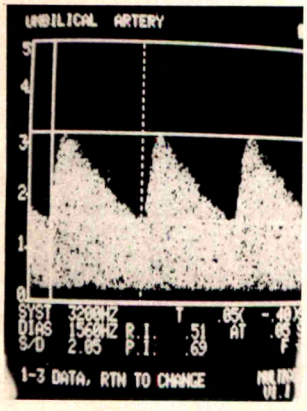
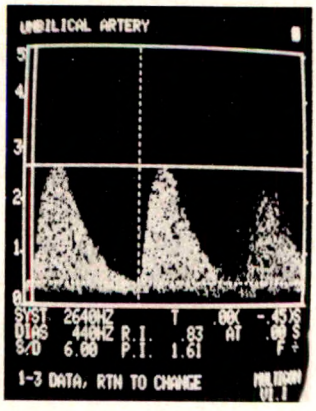
500A™ UMBILICAL-UTERINE ARTERY DOPPLER SPECTRUM ANALYZER

LETS YOU EVALUATE

UTEROPLACENTAL PERFUSION BY SPECTRUM ANALYSIS OF UMBILICAL AND MATERNAL UTERINE ARTERY DOPPLER WAVEFORMS



CLINICAL RESULTS[1-8] SHOW THAT YOU CAN:



- DETECT *IUGR* FROM 20 WEEKS IN SINGLETON PREGNANCIES AND 30 WEEKS IN TWIN PREGNANCIES
- USE UTERINE ARTERY WAVEFORMS IN THE MANAGEMENT OF MATERNAL PREECLAMPSIA
- USE UMBILICAL ARTERY VELOCITY WAVEFORMS IN THE MANAGEMENT OF DIABETIC PREGNANCIES

Umbilical and uterine artery waveforms are easily obtained from early pregnancy on. Low power continuous wave Doppler spectrum analysis is used in a simple test to measure the peripheral resistance in the placental circulation. This resistance is measured by taking the ratio of the systolic to diastolic (S/D) velocity. The S/D ratio is compared to established normal values to determine the presence of abnormal resistance.

The Model 500A™ automatically computes the systolic to diastolic ratio as well as resistance and pulsatility indices.

Normal Umbilical Waveform
S/D = 2.05

Abnormal Umbilical Waveform
S/D = 6.00

HOW MANY NEW DRUG ADDICTS HAVE YOU DELIVERED?

Even one more addict
adds to the staggering number of drug abusers
in our society. You, as a physician, are in a unique position to
help reduce this number. Just ask your patient a simple question during
her initial workup: *Are you using drugs?* Asking about drug use is no more an
invasion of privacy than asking about exposure to German measles. It's
just as important to her baby's health. And knowing about it may
prevent serious problems for you, mother, and baby. Help
free this generation—and the next—from drugs.
Remember...

You'll never know unless you ask.

and PREMARIN®

Proven benefits beyond relief of vasomotor symptoms

No other estrogen proven effective for osteoporosis

Only conjugated estrogens tablets have established efficacy in both osteoporosis[1] and vasomotor symptoms* at 0.625 mg/day. No other estrogen, oral or transdermal, has established clinical evidence or minimum effective dose in both indications.

No estrogen proven safer

PREMARIN is the most extensively tested estrogen, with an unsurpassed record of long-term safety.
And clinical evidence shows a significantly reduced risk of endometrial hyperplasia when cycled with a progestin.[2]

PREMARIN®
(conjugated estrogens tablets)

Most trusted for more reasons

*PREMARIN is indicated for moderate-to-severe vasomotor symptoms.

Please see following page for brief summary of prescribing information.

For moderate-to-severe vasomotor symptoms and for osteoporosis

PREMARIN®

For atrophic vaginitis

PREMARIN®
(conjugated estrogens)

Vaginal Cream

0.625 mg/g

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.
Three independent, case-controlled studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case-controlled studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semi-annual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equi-estrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.
The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing, in later life, a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1,000 exposures. Furthermore, a high percentage of such exposed women (from 30% to 90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case-controlled study estimated a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than 1 per 1,000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: PREMARIN (conjugated estrogens tablets, USP): Moderate-to-severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms and they should not be used to treat such conditions.) Osteoporosis (abnormally low bone mass). Atrophic vaginitis. Kraurosis vulvae. Female castration.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Concomitant Progestin Use: The lowest effective dose appropriate for the specific indication should be utilized. Studies of the addition of a progestin for 7 or more days of a cycle of estrogen administration have reported a lowered incidence of endometrial hyperplasia. Morphological and biochemical studies of the endometrium suggest that 10 to 13 days of progestin are needed to provide maximal maturation of the endometrium and to eliminate any hyperplastic changes. Whether this will provide protection from endometrial carcinoma has not been clearly established. There are possible additional risks which may be associated with the inclusion of progestin in estrogen replacement regimens. (See PRECAUTIONS.) The choice of progestin and dosage may be important; product labeling should be reviewed to minimize possible adverse effects.

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (see Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: Estrogens have been reported to increase the risk of endometrial carcinoma (see Boxed Warning). However, a recent large, case-controlled study indicated no increase in risk of breast cancer in postmenopausal women. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown that there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. Users of oral contraceptives have an increased risk of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis, thromboembolic disorders, or in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease. Large doses (5 mg conjugated

Benign hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has been reported in women taking estrogen-containing oral contraceptives. Increased blood pressure may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use. A worsening of glucose tolerance has been observed in patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Oral contraceptives appear to be associated with an increased incidence of mental depression. Patients with a history of depression should be carefully observed. Pre-existing uterine leiomyomata may increase in size during estrogen use. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, metabolic bone diseases associated with hypercalcemia, or in young patients in whom bone growth is not yet complete. If concomitant progestin therapy is used, potential risks may include adverse effects on carbohydrate and lipid metabolism.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.

d. Impaired glucose tolerance.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. However, in a recent, large case-controlled study of postmenopausal women there was no increase in risk of breast cancer with use of conjugated estrogens.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy, including oral contraceptives: breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis, change in cervical erosion and in degree of cervical secretion; cystitis-like syndrome; tenderness, enlargement, secretion (of breasts); nausea, vomiting, abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persist when drug is discontinued; erythema multiforme; erythema nodosum; hemorrhagic eruption; loss of scalp hair; hirsutism; steepening of corneal curvature; intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea, and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or taper medication should be made at three- to six-month intervals.

2. *Given cyclically:* Osteoporosis. Female castration. Osteoporosis —0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off). Female castration—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Patients with an intact uterus should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (eg, three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

LEVLEN™

(Levonorgestrel 0.15 mg and ethinyl estradiol 0.03 mg tablets)

The lowest total hormonal dose in a monophasic OC formula

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptom of serious disease and discontinue oral contraceptive therapy when appropriate. The physician should be aware of the complete prescribing information for this product. Please also see brief summary of prescribing information on the next page.

BERLEX™ Dedicated to innovation in OB/GYN medicine

LEVLEN™ 28
LEVLEN™ 21

(Levonorgestrel 0.15 mg and ethinyl estradiol 0.03 mg tablets)

BRIEF SUMMARY

Each Levlen tablet contains 0.15 mg of levonorgestrel (d (-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.03 mg of ethinyl estradiol (19-nor-17 α-pregna-1,3,5 (10)-trien-20-yne-3,17-diol) (7 pink inert tablets are included in Levlen 28).

Indications and Usage—Levlen is indicated for the prevention of pregnancy in women who elect to use OCs as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only OCs have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. (The rates given for Pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only OCs are used), and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. However, in progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in women who are not receiving OCs, since the drugs are more effective in preventing intrauterine than ectopic pregnancies.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination being performed.

2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

Information for the Patient—See patient package labeling.

Laboratory Tests—1. The pathologist should be advised of OC therapy when relevant specimens are submitted.

2. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs:
a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thryoid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis, Mutagenesis, Impairment of Fertility—See "Warnings" section #3, 4 and 5 for information on carcinogenesis, mutagenesis and impairment of fertility.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings." Because of the potential for adverse reactions in nursing infants from OC tablets, a decision should be made whether to discontinue the drug, taking into account the importance of the drug to the mother.

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis; pulmonary embolism; coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; benign hepatomas; congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally; gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome; cataracts; changes in libido; chorea; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; vaginitis; porphyria; hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Levlen must be taken exactly as directed and at intervals not exceeding 24 hours.

Any time the patient misses 1 or 2 light-orange tablets, she should also use another method of contraception until she has taken a light-orange tablet daily for 7 consecutive days.

For full details on dosage and administration, see prescribing information in package insert.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the *American Journal of Obstetrics and Gynecology* conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1982;96(6):766-71. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C. V. Mosby Company or the Editors on request.

Manuscripts should be submitted to one of the three Editors as follows: (1) Dr. Brewer—all articles originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians; (2) Dr. Zuspan—articles from the northeastern quadrant of the United States, Japan, Israel, Italy, and England, articles written for Clinical Opinion and Current Development, and Letters to the Editors; (3) Dr. Quilligan—articles from the north central states (including Ohio), states west of the Mississippi, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Quilligan is responsible for articles from the Society for Gynecologic Investigation. Manuscripts should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033. Dr. Zuspan is responsible for articles from The Society of Perinatal Obstetricians. Manuscripts should be submitted to Dr. John A. Read, 9102 Lake Steilacoom Point Road, S.W., Tacoma, WA 98498.

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. **Therefore, all manuscripts must be accompanied by the following written statement, signed by one author:** "The undersigned author transfers all copyright ownership of the manuscript [title of article] to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

When submitting a manuscript, an author should include, if applicable, a full statement about all submissions and prior reports in any medium that might be regarded as prior or duplicate publication of the same or similar work. Copies of such material should be included with the submitted manuscript. Articles previously published in another language will not be considered.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority. Articles dealing with human experimentation that require local institutional approval must have this approval prior to submission of the article for publication and it should be so indicated in the Methods section. Reports of experiments on animals must indicate which guidelines for the care and use of the animals were followed.

Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Edi-

tor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality copies of the manuscript and three glossy prints of illustrations are required.

Manuscripts must be typed double spaced on one side only on 22 by 28 cm (8 1/2 by 11 inch) white bond paper with 1 inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, abstract, body of text, references, legends, and tables.

Title page. The title page should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of all authors and their highest academic degree (both M.D. and Ph.D. are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; acknowledgement of source(s) of support; presented line, if applicable; disclaimers, if any; name and address of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name and address of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Abstract page and key words/phrases. On manuscript page two is the abstract, also typed double spaced with the required margins and headed by the title of the article and author(s) name(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations since the emphasis is on the "action" rather than the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods section* describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results section* present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your observations to those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment section* state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number, except for case reports and brief communications, limited to 2, and Current Development, for which there is no limit. Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Illustrations and tables. A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for color reproduction. For color photographs, submit original transparencies and two sets of unmounted prints on glossy paper with good color balance. For black and white illustrations, submit three sets of 3 by 4 inch (minimum) to 5 by 7 inch (maximum) unmounted glossy photographic prints. Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with author(s) name(s), title of article, number, and top marked clearly). Do not use paper clips. Legends must accompany all figures; type double spaced on a single sheet of paper if possible and number with manuscript in sequence after the references. Titles should be included in the legend, *not* on the print.

All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black and white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Illustrations will be returned only on the author's request.

Tables should be typed on separate sheets of paper and

Estimating length of manuscript

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200 word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7 page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double spaced with the required 1 inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 typed words in manuscript. Thus if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

included at the end of the text, one to a page. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table and each column precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Illustrations and tables should supplement, not duplicate, the text; presentation in either one or the other will suffice.

Permissions and photographic consent. Previously published tables and figures must be correctly referenced and written permission from the copyright holder included with the manuscript. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for a regular article.

Clinical Opinion. Limit of 3000 words, 16 references. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double spaced. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60.00 U.S. and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints. Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications. Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, or call Journal Advertising Production Manager (314) 872-8370.

Checklist

—Letter of submission
—Copyright transfer letter
—Original and two xerographic copies of manuscript
—Title page
—Title of article
—Full name(s) and affiliations of author(s)
—Author to whom correspondence is to be sent
—Reprint request line or line stating reprints not available
—Short title
—Abstract (double spaced), 3 to 5 key words/phrases
—Article proper (double spaced)
—References (double spaced), on a separate sheet
—Legends (double spaced), on a separate sheet
—Tables (double spaced), each on a separate sheet
—Illustrations, properly labeled (three copies of glossy prints)
—Permission to reproduce published material

Fellowships

American Board of Obstetrics and Gynecology approved fellowship training programs in obstetrics and gynecology subspecialties: Gynecologic Oncology; Reproductive Endocrinology; Maternal-Fetal Medicine

CATEGORY State: City Institution	Number of approved positions	Director of program
GYNECOLOGIC ONCOLOGY		
Alabama: Birmingham

CHIEF OF OBSTETRICS/ GYNECOLOGY

St. Joseph Mercy Hospital, a unit of Catherine McAuley Health Center in Ann Arbor, Michigan, is seeking a Chief of OB/GYN. This position is for an active, practicing Obstetrician/Gynecologist who plans to continue active practice, as well as administer the Department of OB/GYN and serve as Director of a free standing, fully accredited surgery residency program. The hospital is a 554 bed teriary care community hospital with affiliations with a major university medical center. The applicant must be Board Certified in OB/GYN. Academic credentials and experience participating in the direction of a OB/GYN residency program will also be necessary.

Address inquiries and send CV to:
Jill Philp, Coordinator
Catherine McAuley Health Center
P.O. Box 995
Ann Arbor, Michigan 48106
(313) 572-3850

UCLA-INTERCAMPUS MEDICAL GENETICS TRAINING PROGRAM

The UCLA Inter-campus post-doctoral research training program in Medical Genetics utilizes the research and clinical resources of its affiliated campuses and teaching hospitals. This program is open to academically oriented applicants with the M.D., Ph.D., D.D.S. or equivalent degrees. A wide variety of research training opportunities in molecular, biochemical, immuno-, cancer, cyto-, somatic cell, population and clinical genetics are available. The program also meets all the requirements of the American Board of Medical Genetics. Clinical genetics fellowships are also available at each of the affiliated hospitals. Application forms are available from David Rimoin, M.D., Ph.D., Department of Pediatrics, Cedars-Sinai Medical Center, 8700 Beverly Blvd., Los Angeles, CA 90048.

OBSTETRICIAN-GYNECOLOGIST WEST VIRGINIA

Excellent opportunity for a Board Certified or Board Eligible OB/GYN. North Central Mountain area of West Virginia-Davis Memorial Hospital, a modern 130-Bed JCAH facility is actively recruiting an OB/GYN wishing to establish a solo practice. The practice will serve a population of 80,000+ people. Davis Memorial is an expanding sole community provider. Lucrative first year guarantee plus office space, staff, malpractice, etc.

Elkins offers an excellent quality of life and is within a ninety minute drive of four major ski resorts. Outstanding outdoor recreational activities abound. A private four year liberal arts college provides many cultural benefits.

Please address inquiries and CVs to:

Elkins, West Virginia 26241
Phone: 304/636-3300 Ext. 150

OBSTETRICIAN/ GYNECOLOGIST

Outstanding opportunity for experienced BC/BE OB-GYN physician to associate with Kaiser Permanente's Kansas City Region. Academically affiliated program with housestaff support, competitive salary and benefit structure including malpractice coverage, family oriented metropolitan area.
Send CV to:

Larry McDonald, M.D.
4240 Blue Ridge Blvd. Suite 1000
Kansas City, MO 64133

816/737-2800

We're staffing up with physicians who share our priorities.

At Maxicare, our first priority is our patients.

And, because many of them wanted complete medical facilities in one location, we've expanded the Maxicare system to include medical centers.

Which is why we're looking for dedicated physicians in OB/GYN.

Maxicare is a national organization. In fact, we're the largest publicly-held HMO in the country. So we can offer generous salaries, vacations, and retirement plans.

Not to mention paid malpractice insurance. Continuing medical education opportunities and area training programs. And the opportunity to work with the very latest technology.

At Maxicare, we care more about our patients than anything else in the world.

But our staff runs a close second.

Contact Physician Placement, (213)568-9000.

Maxicare™

The very best of health.™

Cefizox®

brand of

sterile ceftizoxime sodium and ceftizoxime sodium injection

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

INDICATIONS

'Cefizox' is indicated in the treatment of infections due to susceptible strains of the microorganisms listed below:

LOWER RESPIRATORY TRACT INFECTIONS caused by *Streptococcus* sp. including *S. pneumoniae* (formerly *D. pneumoniae*), but excluding enterococci; *Klebsiella* sp.; *Proteus mirabilis; Escherichia coli; Haemophilus influenzae* including ampicillin-resistant strains; *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Serratia* sp.; *Enterobacter* sp.; and *Bacteroides* sp.

URINARY TRACT INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Escherichia coli; Pseudomonas* sp. including *Ps. aeruginosa; Proteus mirabilis; P. vulgaris; Providencia rettgeri* (formerly *Proteus rettgeri*) and *Morganella morganii* (formerly *Proteus morganii*); *Klebsiella* sp.; *Serratia* sp. including *S. marcescens; Enterobacter* sp.

GONORRHEA. Uncomplicated cervical and urethral gonorrhea caused by *Neisseria gonorrhoeae.*

INTRA-ABDOMINAL INFECTIONS caused by *Escherichia coli; Staphylococcus epidermidis; Streptococcus* sp. (excluding enterococci); *Enterobacter* sp.; *Klebsiella* sp.; *Bacteroides* sp. including *B. fragilis;* and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

SEPTICEMIA caused by *Streptococcus* sp. including *S. pneumoniae* (formerly *D. pneumoniae*), but excluding enterococci; *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Escherichia coli; Bacteroides* sp. including *B. fragilis; Klebsiella* sp.; and *Serratia* sp.

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Staphylococcus epidermidis; Escherichia coli; Klebsiella* sp.; *Streptococcus* sp. including *Streptococcus pyogenes* (group A beta-hemolytic), but excluding enterococci; *Proteus mirabilis; Serratia* sp.; *Enterobacter* sp.; *Bacteroides* sp. including *B. fragilis;* and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

BONE AND JOINT INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Streptococcus* sp. (excluding enterococci); *Proteus mirabilis; Bacteroides* sp.; and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

MENINGITIS caused by *Haemophilus influenzae.* 'Cefizox' has also been used successfully in the treatment of a limited number of pediatric and adult cases of meningitis caused by *Streptococcus pneumoniae.*

'Cefizox' has been effective in the treatment of seriously ill, compromised patients, including those who were debilitated, immunosuppressed or neutropenic.

Many infections caused by aerobic gram-negative organisms and by mixtures of organisms resistant to other cephalosporins, aminoglycosides, or penicillins respond to treatment with 'Cefizox'.

Because of the serious nature of some urinary tract infections due to *Ps. aeruginosa* and because many strains of *Pseudomonas* species are only moderately susceptible to 'Cefizox', higher dosage is recommended. Other therapy should be instituted if the response is not prompt.

Susceptibility studies on specimens obtained prior to therapy should be used to determine the response of causative organisms to 'Cefizox'. Therapy with 'Cefizox' may be initiated pending results of the studies; however, treatment should be adjusted according to study findings. In serious infections 'Cefizox' has been used concomitantly with aminoglycosides (see Precautions). Before using 'Cefizox' concomitantly with other antibiotics, the prescribing information for those agents should be reviewed for contraindications, warnings, precautions and adverse reactions. Renal function should be carefully monitored.

CONTRAINDICATIONS

'Cefizox' is contraindicated in persons who have shown hypersensitivity to cephalosporin antibiotics.

WARNINGS

BEFORE THERAPY WITH 'CEFIZOX' IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. THIS PRODUCT SHOULD BE GIVEN CAUTIOUSLY TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

***Pseudomembranous colitis* has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who developed diarrhea in association with antibiotic use.** Treatment with broad-spectrum antibiotics alters normal flora of the colon and may permit overgrowth of *Clostridia.* Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin *in vitro.* Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C. difficile.* Other causes of colitis should also be considered.

PRECAUTIONS

General: As with all broad-spectrum antibiotics, 'Cefizox' should be prescribed with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Although 'Cefizox' has not been shown to produce an alteration in renal function, renal status should be evaluated, especially in seriously ill patients receiving maximum dose therapy. As with any antibiotic, prolonged use may result in overgrowth of nonsusceptible organisms. Careful observation is essential; appropriate measures should be taken if superinfection occurs.

Drug Interactions: Although the occurrence has not been reported with 'Cefizox,' nephrotoxicity has been reported following concomitant administration of other cephalosporins and aminoglycosides.

Pregnancy: (Category B.) Reproduction studies have been performed in rats and rabbits and have revealed no evidence of impaired fertility or harm to the fetus due to 'Cefizox'. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Labor and Delivery: Safety of 'Cefizox' use during labor and delivery has not been established.

Nursing Mothers: 'Cefizox' is excreted in human milk in low concentrations. Caution should be exercised when 'Cefizox' is administered to a nursing woman.

Infants and Children: Safety and efficacy in infants from birth to six months of age have not been established. In children six months of age and older, treatment with 'Cefizox' has been associated with transient elevated levels of eosinophils, SGOT, SGPT and CPK (creatine phosphokinase). The CPK elevation may be related to I.M. administration.

ADVERSE REACTIONS

Ceftizoxime is generally well tolerated; the *most* frequent adverse reactions (*greater than* 1%, but less than 5%) are: *Hypersensitivity*—Rash, pruritus, fever. *Hepatic*—Transient elevation in SGOT, SGPT and alkaline phosphatase. *Hematologic*—Transient eosinophilia, thrombocytosis. Some individuals have developed a positive Coombs test. *Local*—Injection site—Burning, cellulitis, phlebitis with I.V. administration, pain, induration, tenderness, paresthesia.

Less frequent adverse reactions (*less than* 1%) are: *Hypersensitivity*—Numbness has been reported rarely. *Hepatic*—Elevation of bilirubin has been reported rarely. *Renal*—Transient elevations of BUN and creatinine have been occasionally observed with ceftizoxime. *Hematologic*—Anemia, leukopenia, neutropenia and thrombocytopenia have been reported rarely. *Genitourinary*—Vaginitis has rarely occurred. *Gastrointestinal*—Diarrhea; nausea and vomiting have been reported occasionally. Symptoms of pseudomembranous colitis can appear during or after antibiotic treatment. (See Warnings.)

HOW SUPPLIED

Cefizox (sterile ceftizoxime sodium, FSK) is supplied in vials equivalent to 1 gram or 2 grams of ceftizoxime; in "Piggyback" Vials for I.V. admixture equivalent to 1 gram or 2 grams of ceftizoxime.

Cefizox (ceftizoxime sodium injection, FSK) as a frozen, sterile, nonpyrogenic solution in plastic containers—supplied in 50 ml. single-dose containers equivalent to 1 gram or 2 grams of ceftizoxime, in 5% Dextrose (D5W). Do not store above -20°C.

'Cefizox' supplied as a frozen, sterile, nonpyrogenic solution in plastic containers is manufactured for Fujisawa SmithKline Corporation by Travenol Laboratories, Inc., Deerfield, IL 60015.

CLINICAL SECTION

Clinical Opinion

Stress in residency: Proposals for solution

Preston V. Dilts, Jr., M.D., and Stephen L. Dilts, M.D., Ph.D.

Ann Arbor, Michigan, and Denver, Colorado

Current problems leading to excessive stress in residency are presented and are compared with those of a generation ago. Solutions are proposed that can be summarized as follows: (1) commitment by the program director and chairman to resolving stress in residency and (2) flexibility by the American Board of Obstetrics and Gynecology and the Residency Review Committee. A general discussion is presented. (AM J OBSTET GYNECOL 1987;157:1093-6.)

Key words: Stress, residency, substance abuse

Although an increasing number of papers in recent years have discussed stress during residency training, little has been specifically written about residents in obstetrics and gynecology. A survey of residency training programs in six medical specialties indicated that obstetrics and gynecology residencies rank low in offers of support that would help them cope with the stress of postgraduate training.[1] Most residency directors and department chair persons are aware of depression, substance abuse, and suicide attempts in their residency groups. It is time for the specialty of obstetrics and gynecology to examine this problem from the general perspective of factors that affect residents in any specialty and from the unique perspective of obstetrics and gynecology. For years the stresses of residency training have included identity crisis, sleep deprivation, financial problems, and marital problems; however, we believe that new factors make these stresses more acute and will be discussed in this article.

General residency stresses

Finances. Financial problems have become a major stress, with the average medical student incurring a debt of $32,000, even commonly as high as $40,000.[2] This is a staggering figure, which presents an additional stress today because traditional sources for subsidizing such debts are unavailable. Young physicians find banks much less willing to loan than they use to, perhaps because they feel that physicians manage their money poorly or more likely because the future financial strength of a physician is not as bright as in the past. Even though resident salaries have increased substantially in the past 20 years, it has not been enough to make a significant difference. In 1966, a postgraduate year IV resident earned $4,000, which translates into $19,000 today. In contrast, a PGY IV resident today earns $27,000 but has a much larger debt service to manage. Salaries and benefits may be negotiated by a union (House Officer Association), whose management has little relationship with educational realities.

Other indirect sources of financial support in the past have also disappeared. In large communities, the hospitals often owned or managed an apartment building, which allowed most of the house staff and their families to live in the same facility so that there was a support network for the residents and their families. These facilities were usually offered inexpensively and helped subsidize the lower salaries. Today's residents are scattered throughout their communities in less friendly rentals or expensive mortgaged homes. The support is lacking and problems are compounded.

Moonlighting was uncommon in the past because few jobs were available and it was frequently prohibited.

From the Department of Obstetrics and Gynecology, University of Michigan Medical Center, and the Division of Psychiatric Services, Denver General Hospital.

Reprint requests: Preston V. Dilts, Jr., M.D., University of Michigan Medical Center, 1500 E. Medical Center Drive, Women's Hospital L2120/0270, Ann Arbor, MI 48109-8123.

Jobs such as insurance physicals, at $5 to $15 apiece, were not a very productive way to earn money. Emergency room jobs were rare at that time. Today the house officer has a large number of sites at which to moonlight, providing some income but interfering greatly with family well-being and adding the stress of professional liability.

Finally, residents must be affected by the predictions for a gloomy economic future in the United States. Inflation makes retirement and health care plans unreliable. Recession or depression can destroy any plans. Income is predicted to flatten or fall.

Substance abuse. The American Medical Association[3] estimates that at least 10% of physicians are now or will be alcoholics or drug addicts. A survey of residents at Columbia Presbyterian Medical Center in New York showed that 12.7% were likely to have an alcohol problem.[4] The work of McAuliffe et al.[5,6] demonstrates the increasing use of psychoactive drugs among younger physicians since recreational drug use became more popular in the 1960s. In their studies, more than half of young physicians had used psychoactive drugs, including recreational use of marijuana and cocaine and self-treatment with tranquilizers or opiates. They found that 10% of physicians reported current regular drug use (once a month or more often) and that 3% were drug dependent.[5] Alcohol has been the traditional recreational substance of choice during the training years and has led some to drug abuse and alcoholism. Clearly, a new factor is the increasing social acceptance of recreational drug use and the inherent risks for developing drug abuse problems and addiction, especially with the availability of samples of addictive drugs such as minor tranquilizers.

Marital discord. Residency is a time of intense personal transition with the added stress of long work hours that take residents away from their families. Marital tension may result and is an additional stress that may contribute to impairment of performance. As more women enter our residency programs, it is important to realize that the divorce rate for female physicians is higher than for male physicians.

Since 80% of female physicians marry other professionals, dual-career issues have become increasingly prominent and present the problems of finding positions in the same area for both partners, difficulties in planning leisure time together, and difficulties in arranging for pregnancy and child care. These stresses are even worse if the professional is also a resident.[7]

Sleep deprivation. Call schedules today are supposedly easier than in the past and usually occur every third or fourth night; however, patient care is now much more stressful with more opportunities for mistake. The increasing complexity of medical care with a continuing trend toward subspecialization has made decision making while on call difficult and frustrating since the resident may feel unprepared to face these decisions alone. Residents are acutely aware of the increasing number of malpractice suits and skyrocketing malpractice insurance premiums in obstetrics and gynecology, and their worries about these add another burden to the decision-making process while alone on call. These factors lead to increased on call stress and the consequences of such stress. Although overwork and fatigue are not thought to be causes in and of themselves for substance abuse, depression, and suicide, they are increasingly considered contributing factors that may be the straw that breaks the camel's back.[8] Recent evidence indicates that being on call significantly increases pulse rate and blood pressure.[9]

Identity. Residency training is the period when important developmental tasks of early adult life are consolidated, including work, play, mentor relationships, attitudes toward care of one's body, and concerns about time limitations and death.[10] This developmental process is greatly affected by the areas of stress that have already been discussed. In addition, the future of our house officers is much less certain than it previously was. In the past we could hang out a shingle in a place where we wanted to live and were virtually guaranteed of success. This is no longer true, and many of our house officers have trouble finding a practice position. In fact, the practice of opening a practice has now changed into looking for a job. The atmosphere is different, the opportunities are less, and the future is not as bright.

The professional world in which we live is certainly less happy than it was in the past. Patients are much more argumentative and in some cases threatening. The charge of sexual abuse can occur at any time. The spectre of professional liability, whether frivolous or not, is great. Risk management and morbidity and mortality discussions involve house staff much more frequently than they did in the past. The horror of contracting diseases such as sexually transmitted disease, herpes, or acquired immune deficiency syndrome from patient care can be overwhelming. Advocate groups for the poor, the handicapped, and others can be disruptive and even threatening.

Subspecialization is rapidly occurring in all specialties with an increasing emphasis on board certification and subspecialty boards. Subspecialty education can disrupt residencies and the decision whether to subspecialize adds stress. Board examinations are more comprehensive and the failure rate for the American Board of Obstetrics and Gynecology is still 20%.

Mentor relationships are still important, but as medical life becomes increasingly complicated, these relationships are more difficult to form. Faculty and chair persons today move more frequently, which again in-

terferes with the resident's ability to form faculty relationships.

Overall, the resident's developmental needs are impaired by the factors discussed. This leads to a much less positive attitude about the future and makes it difficult for residents to cope with the stresses they encounter.

Solutions

There are no easy solutions to this problem; however, change can be achieved if the necessary steps are taken in a careful and planned fashion, which will result in a slow evolutionary process in medical training in the United States. Important barriers may hinder programs from adequately addressing the problems of resident stress and impairment.[11] These include a lack of focus on primary prevention, problems in the supervisory process that place a priority on teaching and not on issues of residency stress, resident resistance to admitting they are under stress and are in need of help, and stigmatization and rejection of residents by faculty and other residents when stress is discussed. Clearly, any major change in residency training will involve a drastic change in attitudes and priorities about what is important in residency training. Attitudes such as these will take time to modify. The important point is that the time to start is now.

We propose the following solutions to the problem of residency stress:

1. There must be a total commitment to change the residency program by the program director and faculty. This commitment would be directly observable if the residency director and chair person were the same individual. If not, the residency director and chair person must work so closely that the authority of the chair is visibly vested in the residency director. With this commitment and leadership, faculty and residents will know reduction in residency stress is a priority.
2. Mentors are a recently rediscovered phenomenon in medical education. It would be helpful in residency training to use this model and assign house officers to the chair person or residency director for the first year with the requirement they must select a different faculty member as mentor at the end of that year. This allows the house officer to get to know various faculty members during the first year and choose someone whom they respect and with whom they have a rapport to work with throughout the remainder of the residency. The mentor relationship can provide support, role modeling, and advice about clinical, professional, and personal issues.
3. Faculty and senior residents must vigorously organize support groups. Even though residents live throughout the community, it is important that they are able to provide mutual support in facing professional stresses, illnesses, and family issues such as pregnancy, child care, and recreational time.
4. House officers must be involved in decisions concerning their residency. Many times they are more aware of problems than are the faculty and their ideas are valuable A committee concerned with the well-being of the house staff should be formed to give resident representatives a formal forum in which to present problems and ideas for solutions to the residency director and faculty representatives. Such committees must have power for the residents to feel that they are able to work effectively with their problems.[12] Within general guidelines set by the program director and the certifying agencies, residents (chief administrative resident) should arrange call and vacation schedules. Family time can be enhanced, and coordination with spouse call or work schedules can be arranged.
5. Institutions should provide counseling on a readily available basis, and counseling must be private and confidential.[13] Confidentiality is enhanced if psychotherapy is available off campus.
6. Recent national publicity is indicative of the crisis we have reached in the area of fatigue and its effect on house officer performance and education. The call schedule system must be changed. If residents are awake most of the night, they must be allowed to go home the next morning to sleep. If they are not awake all night, they should be allowed to go home the next morning to freshen up and return for an afternoon of less stressful duties such as research or paperwork.
7. Residents should be involved frequently in social events for the whole department to relax and feel the involvement and support of the faculty.
8. Finally, we need to take a serious look at how residency training is structured. It is mandated by both the American Board of Obstetrics and Gynecology, Inc. and the Residency Review Committee. There must be 4 years of education after medical school; 36 months of this must be in obstetrics and gynecology. There can be no more than 6 weeks' absence during any year of residency or makeup must occur. The resident must see an unwritten minimum number of cases for the residency to be approved. This same model is applied to all programs and all residents.

Programs must be allowed to vary. Those with large numbers of deliveries and/or surgical cases can graduate a resident in 4 years, the minimum time required to master a complex multidisciplinary specialty such as

Obstetrics and Gynecology. Programs with smaller numbers of cases may require 5 or 6 years to graduate a resident. By the same token, residents must be allowed to vary the structure of their training according to their level of skill. The length of training for an individual resident should be flexible without penalty from the Residency Review Committee or American Board of Obstetrics and Gynecology. Currently a resident can be held back only with prior permission by the Residency Review Committee, and two residents cannot be held back simultaneously. These requirements force residency programs to graduate residents on time whether or not they are ready for independent practice. Variable programs may lead to legal problems with claims of discrimination; however, if educational objectives are clearly written, carefully followed, and documented in writing, variations in resident training should be allowable.

Residency stress is a significant problem today and differs substantially from the past. We have suggested solutions for resolution of this problem, but it is clear that the solutions are expensive and will take years to implement. If we are committed to make residency stress a priority, barriers such as financial cost can be overcome.

The pregnant brain dead and the fetus: Must we always try to wrest life from death?

Erich H. Loewy, M.D.
Peoria and Chicago, Illinois

This article deals with the ever more timely and often vexing topic of maintaining a brain-dead mother as an incubator for her developing offspring. It explores the issue by: (1) reviewing the history of the problem and the "state of the art" today, (2) examining the moral problem of using brain-dead persons as incubators for potential or actual others, (3) searching for moral differences between maternal death early or late in pregnancy, and (4) presenting a possible resolution in such tragic cases. It concludes that (1) a moral necessity to deliver viable infants from brain-dead mothers exists; (2) the farther from viability brain death occurs, the more maintaining the mother as an incubator resembles experimental therapy with its imperative for careful, informed consent; (3) experimental therapy not being morally necessary, its proceeding under these tragic circumstances should invoke community support for the next of kin in dealing with the immediate and long-term costs; (4) all ethical problems proceed in a context to which the moral actors must be sensitive and one that alters the conclusions made. (Am J Obstet Gynecol 1987;157:1097-101.)

Key words: Brain death in pregnancy, postmortem cesarean section, physician/patient relationship

The current work explores the issue of artificially maintaining a brain-dead pregnant patient long enough that a potentially viable child might be delivered. This ever more timely topic is explored by (1) reviewing the history of the problem and the "state of the art" today; (2) examining the issue of using a brain-dead patient merely as an incubator for a potential other and the difference, if any, between that and an actual other; (3) searching for a moral difference between maternal death early or late in pregnancy; and (4) presenting a possible resolution to such tragic problems.

Historical considerations and the state of the art

Cesarean section was apparently first used to extract a living child from a dead, rather than a living child from a living, mother. Although cesarean section may have been practiced in early antiquity, the history of the procedure as well as the origin of the name is unknown. The legendary Greek physician Asklepios, fathered by Apollo, was supposedly delivered from his dead mother, Koronis, by postmortem cesarean section. Bacchus likewise is said to have been born in this manner.[1] No mention of the procedure appears in the works of Hippocrates, Galen, or Soranus. In the East, and in the fourth century BCE, Susruta's Sushruta Samhita mentions a cesarean section done either in "a woman whose life is in great danger" or "in a woman who is dead."[2] The Babylonian Talmud states that if the mother dies during childbirth, the dead mother's abdomen should be immediately opened to deliver the child.[3] This was the practice during Hellenistic times and the Roman authorities in antiquity (and, in the seventeenth century, Venetian authorities) required that the attempt to deliver the living from the dead be made.[4] According to Pliny the Elder, Scipius Africanus was delivered by successful postmortem cesarean section in 237 BCE.[5]

The origin of the term cesarean section is unclear. The *Encyclopedia Britannica*, in its latest edition, states that Pliny attributed it to the family of Julii whose cognomen Cesare (from *caedere*, the Latin for to cut) originated from this alleged manner of their birth. The stories that claim that it is the method by which Julius Caesar was delivered from his dead mother in 102 BCE are evidently apocryphal. Caesar's mother is known to have been very much alive 40 years after her son's birth.[6] About 700 BCE Numa Pompilius forbade the burial of a pregnant woman before the child was removed,[3, 7] but it is unclear whether that was to rescue a live child or to bury it separately. This decree first became part of the King's Law (Lex Regia) and later part of the Emperor's Law or Lex Caesare. The procedure may thus have been termed the Emperor's (or cesarean) operation.

church, following Roman law, required postmortem cesarean sections so that the infant could be properly baptized and buried. Failure to do this was an ecclesiastically punishable offense.[7] Sicilian law in 1749 held that a physician who failed to try such delivery in case of death during late pregnancy was guilty of murder and King Charles ultimately sentenced a physician to death for that failure.[8] In 1757 Austrian law made the procedure compulsory when pregnancy had advanced beyond 6 months. Ecclesiastical and secular law coincided and both required that the attempt be made.

Historically, cesarean section was first performed in an attempt to extract either a living child from a dead mother or, at least, to provide separate baptism and burial; later, the operation was done in a dying mother to save an infant and only quite recently to save both mother and child (the first such operation being successfully done in 1500 by Jacob Nufer, a Swiss sow gelder).[7,8] Today a new twist has been added: Keeping an otherwise dead but biologically alive mother alive merely to enable a nonviable infant to reach viability has added a new dimension.

In 1961, Ritter[1] reviewed recent experience with postmortem cesarean section and suggested that the procedure is practical, even though the prognosis is not good, after 28 weeks' gestation. Ten years later, Weber[6] conducted a careful review of the literature to date and again concluded that pregnancy under 28 weeks offers little if any chance for success. How many actual cases of successful postmortem cesarean section have occurred is, of course, unknowable. However, a recent review, based on a statement in a textbook dealing with trauma in pregnancy, states that "fewer than 200 successful instances of post-mortem Caesarean section have been reported in the literature."[7] Dillon et al. added two cases of their own and concluded that at less than 24 weeks' gestation no "extraordinary measures for mother or fetus" seem warranted. After that, life support for the mother is indicated until cesarean section is performed at 28 weeks to save the child. Earlier cesarean section is done only if maternal viability cannot be maintained.

Postmortem cesarean section is quite different from deliberately maintaining maternal viability for the sake of the fetus. Until recently, brain death meant inevitable whole-body death; therefore the question was moot. Nowadays maintaining viability is at least theoretically possible. Usually the brain dead are maintained for the few hours needed to harvest organs. Keeping brain-dead persons alive for longer than this appears to be a formidable undertaking. In general, it is believed that even with full ventilator and other medical support, cardiac arrest will occur.[9] The occasion to test this thesis rarely arises. A recent case, in which a brain-dead patient was successfully maintained for 74 days until a court order could be obtained,[10] as well as an even more recent case in which biologic existence was maintained for 64 days so that an infant could be delivered, casts doubt on such a thesis.[11] A permanently vegetative patient or one with an irreversible condition poses similar problems. In a case that deserves mention,[12] a patient who was 6 weeks pregnant was in an irreversible coma after an automobile accident. She was delivered of a living normal infant in the thirty-fourth week of gestation. However, maintaining such existence is an incredibly difficult, time-consuming, and costly venture whose success, while possible, is unlikely.

More recent experience has resulted in questioning of the recommendations that state that at less than 24 weeks' gestation no further efforts to sustain the mother are ever justified. Recently a patient who was 22½ weeks pregnant suffered cardiac arrest secondary to a central nervous system lesion; she was resuscitated but was found to be brain dead. Despite bacteremia, diabetes insipidus, adrenal failure, hypothermia, and hypotension she was maintained on a regimen of hyperalimentation until the successful delivery of a normal baby whose eventual chance for survival was deemed to be excellent.[11] Sporadic cases of this sort are being reported from across the country. It is unknown how many attempts fail to produce viable infants or how many result in stunted or defective offspring.

The brain dead as incubators

When brain-dead mothers are maintained for the sake of possibly producing viable offspring, their bodies are used as incubators. No longer are they, in any sense, used as ends in themselves. Every effort to maintain life and combat disease is done not to benefit the person treated but to benefit another. Such persons have become mere means to another's survival.

The situation then has some similarity to the maintenance of the brain dead for harvesting of organs. However, here the newly dead are maintained only briefly, the organs are quickly removed, and elaborate efforts are rarely needed. When it comes to maintaining a brain-dead mother as an incubator for her developing offspring, the situation is closer to maintaining the brain dead indefinitely to grow tissues, do experiments, or otherwise use them as objects.[13] That is sufficiently problematic to bear closer scrutiny.

The physician/patient relationship, as well as respect for rational beings, would seem to prevent physicians from using patients merely as objects to the ends of others. That would preclude not only maintaining brain-dead mothers as incubators for their potential offspring but also maintaining the brain dead, for whatever time, as organ donors; and yet we intuitively feel that there is a clear distinction between the living and the brain dead that changes the nature of obligation.

The physician/patient relationship is one in which both parties, actually or at least potentially, participate.

In medical practice, this relationship is the central issue surrounded and embodied in a complex skein of other relationships in which one or the other party shares. Relationships with patients are dynamic, growing things. When one of the participants dies, growth stops and dynamics cease. The relationship is transmuted. The central core changes and symbolism takes its place; peripheral considerations, those of family, friends, and staff and the needs of others, become the central reality. The newly dead are of great symbolic value as symbols of former persons, but they are symbols and not reality. Their moral value is secondary rather than primary; they are valued not as entities, which have worth in themselves because they are capable of actual or potential harm or benefit (primary value), but because of their symbolic worth and because of their value for others (secondary value). To conflate symbol with reality, to value the symbol more, is to confuse sentiment with sentimentality.

The growing fetus has real as well as symbolic value. Being, at least potentially, capable of being benefited or harmed, it has primary value; being of value (or disvalue) to another, it has secondary value; standing for renewal, continuity, and the life that may yet arise out of the dead, it has symbolic value. Its interests therefore are greater than the interests of its brain-dead mother whose interests can only be looked at symbolically. The interests that before either favored the mother or, in another view, were equivalent now clearly support the fetus.

The growing fetus has real value as a fetus, secondary value (or disvalue) to another, and symbolic value as a symbol of future sentient life. In relation to the brain-dead mother, it is the "flesh of her flesh" and the "blood of her blood," a matter with different standing from using the brain dead as incubators for body parts or as objects for experimentation. It can be viewed as the biologic continuity of her life and the symbolic continuity of her being. These differences may justify the prolonged use of the newly dead for lengthy periods, in fact, for periods that make them no longer "newly" dead.

When the newly dead are to be used to procure organs for the sake of others, we require either previous informed consent, or at least a lack of dissent, of the newly dead or of the next of kin. We require such consent or allow such dissent out of respect for the symbolism inherent in the newly dead. This is done despite the critical need of an actual other whose very life depends on the donation. Whether this is or is not morally the proper thing to do has been widely discussed in the literature.

Maintaining brain-dead patients briefly for the sake of harvesting their organs to be used by living patients who otherwise would be destined to death or severe disability, differs from maintaining brain-dead patients for a substantial length of time to benefit a potential other. Briefly sustaining biologic function to harvest organs expresses respect for the living and affirms our belief that the newly dead were members of a just community concerned with the welfare of its living members. It is a way of valuing the living more than the dead, reality more than its symbol. Doing that (and allowing individual dissent) honors the memory of the dead, supports their symbolic ongoing membership in the just community, and affirms our ongoing concern for the living. The procedure is trusted and tried and has moved out of the realm of experimental medicine. Maintaining the brain dead briefly in order to harvest organs critically needed for the living is clearly justified.

Maintaining the brain dead for prolonged periods as incubators for potential others is not without inherent problems. The other we seek to enhance is a potential being; the procedure and its results have little precedent to guide us and, furthermore, are enormously time and resource consuming. While, symbolically, the potential being is the "flesh of the flesh" and the "life of the life" of the person that just recently ceased to be, things here stand differently than when the newly dead are briefly maintained to salvage organs.

Moral differences between early and late-stage pregnancies

Our attitude toward the question of moral differences between early and late-stage fetuses directly involves our attitudes toward abortion. However, unlike the abortion argument, an agreement can hope to be achieved. In the abortion argument, the attitude basing its viewpoint on immediate ensoulment or personhood of the newly conceived stands in opposition to the attitude that holds that the interests of the developing fetus (at least prior to central nervous system function) have less force than those of the mother. Here is not the time or place to engage in this interminable and probably fruitless discussion. In general, however, both sides would agree that the embryo, far from being without interests and thus being purely an object to be acted on, has inherent interests. The two sides disagree since one holds the interests of the fetus to be equivalent to those of the mother, whereas the other holds them to have considerably lesser force.

In the case under discussion, the primary interests of the mother, by definition, cannot be invoked; they either do not exist or, at the very most, stand permanently moot. Her value and interests are now secondary (as she is of value to others) and symbolic. This value and these interests stand balanced with those of the developing fetus whose interests, at the very least, are potential and growing.

There is one critical difference, whether one does or does not hold all human life to have "absolute" rights. The current state of the art makes it possible, even if

very difficult, for us to achieve success in producing a viable infant from a brain-dead mother at 24 weeks and remotely possible but excruciatingly difficult to achieve the same results at 22 weeks; the possibilities are entirely unknown earlier than that. Further, while it is quite possible to have not only a viable but also a "normal" fetus at 24 weeks, experience earlier than that is either sparse or entirely absent. That changes the dimensions of the problem.

Resolution

The situation that confronts physicians and institutions today has changed markedly from what it was a few years ago. So has the moral climate. On the one hand, technical advances have enabled physicians to seek their patients' good in much more forceful ways; on the other, that "good" is no longer properly decided by physicians or institutions but is the product of informed deliberation in which all those directly concerned partake. Choices are no longer the sole responsibility of a physician working in a particular institution under its autonomously determined rules. Medicine, as well as the institutions in which medicine operates, has properly become a communal venture, forced to a large extent by economic conditions.

The current problem is not one open to easy, facile, or permanent solutions. Attitudes will and must depend on the feasibility, probability, and, yes, ease of the solutions sought. Stopping support of the brain-dead mother, thereby inevitably causing the death of the fetus, is analogous to abortion only insofar as the fetus is either viable at that time or close enough to viability so that its survival can be reasonably assumed; the farther away from that time it is, the more it is unlike abortion.

Resolution in concrete situations will, to a large extent, depend on the available technology. Feasibility depends entirely on this and, unless a procedure is at least feasible, its moral standing is moot. The probability of success is another variable that strongly affects our approach. An action whose likelihood of success is great (for example, delivering a baby by cesarean section at term from a mother whose heart has just stopped) is an entirely different matter than one unlikely to succeed or one whose outcome is virtually unknown. Further, success here begs definition: Do we mean the delivery of a normal, viable infant or are we willing to settle for a severely damaged one? When an intervention has not been routinely applied, when the venture is fraught with unknown problems ahead, and when risk/benefit ratios remain undefined, the procedure is generally held to be experimental. Experimental procedures require the most careful informed consent. Such consent is "a statement of fidelity between the man who performs medical procedures and the man on whom they are performed."[14] When that one is unable to speak for himself/herself, the next of kin as surrogate traditionally has spoken. The very definition of "informed" is difficult since, by the nature of the undertaking, the person informing often has only little information to give. Outcomes, risks, and benefits are nebulous. Often previous trials, animal experiments, or analogous precedent may tentatively help but "hard" information, by the very definition of the undertaking, which is a venture into the unknown, is unavailable. At times, the best physicians can do is to share their honest ignorance, their concerns, and their doubts. The current problem has little concrete precedent and, at best, there are only a few anecdotal examples to light the way. These are examples of success; failures, by their very nature, usually remain unpublished.

Unless one feels comfortable with late third-trimester abortion, there is little doubt that when the pregnancy is well advanced, for instance, beyond 28 weeks, immediate delivery by cesarean section is indicated. If one finds no moral problems in the abortion of viable infants, that statement may seem less obvious. For the sake of this article, I will maintain that our current communal ethos is sufficiently opposed to the destruction of fully viable infants (except, perhaps, under the most severe conditions of threat to the life of the mother) as to make such a solution not tenable. It follows that when viability is reasonably assured and when delivery does not threaten the life of the mother, delivery should be a matter of routine medical treatment. At 28 weeks and beyond, there is a fair chance for success and a reasonable hope that the infant will be normal. Treatment then is no longer experimental and, barring unusual circumstances, must proceed.

When gestation is shorter, the attempt to maintain brain-dead mothers as incubators for their developing offspring would need to be carefully discussed with the next of kin and would require informed consent. As the length of gestation diminishes, so does our ability to predict outcomes. Procedures more and more approach the innovatively experimental and therefore more and more require consent. That consent, in the nature of things, will be less and less able to be "informed" and more and more speculative. No moral mandate can enjoin one to subject one's patient to experimental therapy; no moral mandate can force patients to accept such treatment. Not maintaining a brain-dead mother as an incubator for her infant in early pregnancy, for instance, before the twentieth week, is no more like abortion than not giving experimental chemotherapy to a dying cancer patient is murder. Maintaining the brain dead as incubators (or giving experimental chemotherapy) is morally permissible when proper consent (consent that makes clear the experimental nature of the undertaking) is obtained, but it certainly is not a moral imperative.

In individual cases, judgments will depend greatly

on the circumstances. When a patient is in her first trimester, when the fetus is, in some probability, assumed to have been severely damaged by the mother's abnormal condition (sustained hypoglycemia may well be such a case), or when other formidable technical problems are present, an attempt to maintain the brain-dead mother as incubator seems, in the current state of medicine, ill advised. As 20 weeks is approached, the possibility of success is ever better even if its likelihood continues to be rather remote. At this point, earnest conversation with the next of kin (rather than a "sportive" attempt to prove a point and to add another case of the "Annals of Unlikely Outcomes") is in order. Here the factors of cost, material and emotional, must have a place. An about to be bereaved father of three children may be in no position to underwrite or undertake an experimental venture that then leaves him with one more child to raise alone. The community has no right to try to persuade the next of kin to participate unless perhaps the community is, at the very least, ready to assume the financial burden of the venture as well as of its consequences. Even then, it is still the next-of-kin's choice and not ours to judge.

At about 24 weeks and with at least some precedent of success, there is still a need for informed consent. Here, where information is at least more available, suggesting to the relatives that an attempt may be worthwhile seems reasonable. Nevertheless, the community and the institutions that represent it should, in decency, stand ready to assume at least the financial burden. Communal duties to assist those struck by disaster or tragedy are, however, another matter and legitimately a separate topic.

Resolution of these tragic cases cannot be made without attention to the situation, its context, and the moral actors involved. Strict criteria denoting moral certitude here, as in most of life, of which medical ethics is but a part, cannot be applied and ambiguity inevitably persists.[15] Denying this reduces ethics to yet another strictly technical exercise that seeks to "apply" ready-made answers to preconceived problems without filtering them through our moral sensibilities. Decisions in particular cases must rely on an interplay among moral actors and their peculiar contexts. In the final analysis our decisions reveal more about us and about the other moral actors involved than they do about the problems themselves. Discretion is the essence of decision making and discretion proceeds in a context and within a historical time frame. Not ultimately and forever right or wrong, decisions represent our groping for truth rather than truth itself. Their moral virtue resides in the agony of decision making rather than in the particular decision itself.

Unintended laparotomy associated with laparoscopic tubal sterilization

Adele L. Franks, M.D., Juliette S. Kendrick, M.D., and Herbert B. Peterson, M.D.
Atlanta, Georgia

Although the complication rate for laparoscopic tubal sterilization is generally low, laparotomy is sometimes necessary to complete the sterilization or manage complications. To better characterize factors that predispose women to unintended laparotomy, we analyzed data from the Collaborative Review of Sterilization. Of the 5027 women undergoing laparoscopic tubal sterilization, 12 had unintended laparotomies to manage complications, whereas 39 women had unintended laparotomies because of technical inability to complete the laparoscopic procedure. Women with prior abdominal or pelvic surgery had an increased risk of unintended laparotomy (relative risk = 10.2, 95% confidence interval = 5.3 to 19.7). Women with a history of intrauterine device use or pelvic inflammatory disease had elevated risks that were not statistically significant (relative risk = 2.2 and 1.5, respectively). Comparative studies of alternative surgical approaches for tubal sterilization are needed to formulate recommendations for women who may be at increased risk of unintended laparotomy associated with the laparoscopic approach. (AM J OBSTET GYNECOL 1987;157:1102-5.)

Key words: Laparoscopic tubal sterilization, laparoscopy complications, tubal sterilization methods

Since 1970 sterilization via laparoscopy has increased dramatically in popularity and now accounts for at least one half of all nonpregnancy-associated tubal sterilization procedures in the United States.[1] The laparoscopic approach has proved safe and effective overall and involves shorter hospital stays than traditional laparotomy.[2] Under some circumstances, however, the sterilization procedure cannot be completed laparoscopically because of technical difficulties or arising complications, which necessitate a laparotomy. Such unintended laparotomies expose women to the surgical risks of both procedures, prolonged anesthesia, and in some cases a second anesthetic and hospitalization.

Several studies have implicated previous abdominal or pelvic surgery, a history of intrauterine device (IUD) use, or pelvic inflammatory disease as possible risk factors for intraoperative difficulties or unintended laparotomy.[3-6] A preliminary analysis of laparoscopic sterilization complications that used the first 3500 women enrolled in the Collaborative Review of Sterilization has been previously published.[7] Results suggested that previous surgery and pelvic inflammatory disease modestly increased the risk of complications, the most common of which was unintended laparotomy.

None of the previous studies have assessed all three of these potential risk factors simultaneously. To better characterize unintended laparotomy and assess these three risk factors, we used data from more than 5000 women enrolled in the Collaborative Review of Sterilization, a multicenter prospective study of the safety and efficacy of female sterilization operations.

Table II. Relative risk of unintended laparotomy by preoperatively known risk factors, women undergoing laparoscopic tubal sterilization, Collaborative Review of Sterilization 1982

Preoperative risk factors	*No. of UL*	*No. of women*	*Rate (%)*	*RR*	*95% CI*
None	8	2377	0.3	1.0	(Referent)
Previous surgery only	21	610	3.4	10.2	(5.3-19.7)
PID only	1	196	0.5	1.5	(0.2-11.9)
IUD only	9	1192	0.8	2.2	(0.9-5.7)
>1	12	652	1.8	5.5	(2.5-12.1)

UL = Unintended laparotomy; RR = rate ratio, or relative risk, comparing each risk group with group without risk factors; CI = confidence interval; PID = pelvic inflammatory disease.

Material and methods

From 1978 to 1982, 5342 women scheduled for laparoscopic tubal sterilization were enrolled from 11 institutions in five cities. All women were 15 to 44 years old and were not pregnant on admission to the medical center. Before the operation, each woman was interviewed with a standard questionnaire. The interview included questions regarding medical history and previous contraception. In our analysis previous surgery was defined as a patient report of any prior surgery involving the abdomen or pelvis. Previous pelvic inflammatory disease was defined as a patient report of having been diagnosed with pelvic inflammatory disease by a physician. Previous IUD use was defined as a patient report of having used an IUD in the past.

Information regarding surgical details was recorded intraoperatively.

Postoperative information was obtained from the hospital record, the first follow-up interview approximately 4 weeks later, and the second follow-up interview at 1 year. Unintended laparotomy was defined as laparotomy within 6 weeks of the laparoscopic procedure, which was performed to manage complications from the laparoscopy or to complete the sterilization.

This definition excluded laparotomies performed for the treatment of pathologic conditions observed at laparoscopy (n = 5), for unrelated disorders (n = 3), and because of equipment malfunction (n = 1). Also excluded were 265 women who underwent concurrent operative procedures (such as ovarian biopsies or drainage of ovarian cysts) that could have led to complications. Dilatation and curettage, routine IUD removal, or lysis of adhesions were not considered concurrent procedures for the purpose of exclusion. Also excluded were 41 women whose histories were incomplete regarding previous surgery, IUD use, or pelvic inflammatory disease. After exclusions, the cohort included 5027 women.

Crude relative risks and test-based confidence intervals were calculated by means of the method of Miettinen.[8] Where the confidence interval does not include 1.0, the results are statistically significant at the $p < 0.05$ level. Logistic regression methods[9] were used to assess potentially confounding effects of age, race, intended method of tubal occlusion, type of anesthesia (local versus general), and obesity.

Results

Fifty-one women from this cohort underwent an unintended laparotomy, which resulted in an overall rate of 1.0%. Thirty-nine laparotomies were performed because of technical problems with the attempted laparoscopic procedure, whereas 12 were performed to manage complications.

Of the 39 laparotomies performed because of technical problems (Table I), 32 resulted from encountering adhesions, hydrosalpinx, or other anatomic distortions, whereas seven resulted from difficulty entering the peritoneal cavity. Among these 39 women, 35 had the laparotomies under the original general anesthesia. Compared with women who did not have a laparotomy, anesthesia time was prolonged (mean 83 versus 26 minutes), and the rate of postoperative complications (fever, transfusion, rehospitalization, and life-threatening event) was increased (11.4% versus 0.6%). The remaining four women underwent laparotomy during a subsequent hospitalization under a second anesthetic (details unavailable).

Among the 12 women with laparoscopic complications (Table I), two required total abdominal hysterectomies and three required bowel resections. A second hospitalization and second anesthetic was necessary in the treatment of six of these 12 women.

Overall, 21% of the women in the entire cohort had a history of prior abdominal or pelvic surgery whereas 35% had a history of IUD use and 10% had a history of pelvic inflammatory disease. These are not exclusive categories. Forty-seven percent of women had none of these potential risk factors.

For both complications and technical problems, the unintended laparotomy rate was higher for women with any of the risk factors than for women without these risk factors. Overall unintended laparotomy rates for each exclusive risk group (Table II) were as follows:

3.4% for previous surgery, 0.8% for IUD use, 0.5% for pelvic inflammatory disease, and 0.3% for women with none of these risk factors. Women with more than one of these risk factors had an unintended laparotomy rate of 1.8%.

The relative risk, or rate ratio, of unintended laparotomy for women with a history of prior abdominal or pelvic surgery relative to women with no risk factors was 10.2 (95% confidence interval = 5.3 to 19.7). For women with a history of IUD use or pelvic inflammatory disease, the increased relative risks of 2.2 and 1.5, respectively, were not statistically significant.

Multivariate analysis adjusting for age, race, intended method of tubal occlusion, anesthesia, and obesity yielded no appreciable alteration in relative risks associated with the three risk factors under investigation.

When a history of prior cesarean section (32% of women with previous surgery as their only risk factor) was evaluated separately from other abdominal or pelvic surgery, the rates of unintended laparotomy were 5.9% for cesarean section only and 2.4% for other surgery only. Compared with women with no risk factors, the risk ratios were 17.5 (95% confidence interval = 8.8 to 34.8) and 7.1 (3.2 to 15.8), respectively. Information was unavailable regarding types of abdominal or uterine incisions for these cesarean sections.

Comment

We addressed the hypothesis that conditions that may predict anatomic abnormality, such as adhesions or adnexal disease, increase the risk of unintended laparotomy as an outcome of laparoscopic tubal sterilization. Our finding of a 10-fold increase in risk for women with previous abdominal or pelvic surgery is consistent with previous studies and helps quantitate long-held clinical suspicion. This elevated risk pertains to women with previous cesarean sections as well as other operations of the abdomen or pelvis.

IUD use was also associated with an increased risk. Although this increase was not statistically significant, our findings are consistent with biologically plausible effects. Among the 1192 women who had only a history of IUD use but did not have pelvic inflammatory disease or prior surgery, nine had unintended laparotomies. Five of these were necessary because of abnormalities consistent with subclinical pelvic inflammatory disease, such as hydrosalpinx.

We believe that the risk associated with pelvic inflammatory disease may have been underestimated because patient histories may not be reliable indicators of previous pelvic inflammatory disease.[10] Furthermore, women who recalled the clinical diagnosis of PID may have been more likely to have received treatment than women who did not. If treatment diminishes pelvic sequelae, the women classified as having pelvic inflammatory disease in our cohort may have been less at risk for unintended laparotomy than women who actually had pelvic inflammatory disease but did not recall it.

In summary, data consistently show that some women are predictably at higher risk of technical problems or complications during laparoscopic tubal sterilization. Whether any alternative surgical approach can be recommended for them remains unresolved. There is currently some enthusiasm for two less commonly used surgical approaches: open laparoscopy,[11] which is done entirely under direct vision, and minilaparotomy,[12-14] which involves a small (2 to 5 cm) laparotomy incision. Although both of these procedures may seem promising to some, insufficient epidemiologic data exist to compare them with traditional laparoscopy or laparotomy.

Therefore the important question of whether these procedures offer any advantage to women with abdominal or pelvic abnormalities cannot presently be answered. To address this question will require study of a large number of tubal sterilizations performed by these alternative techniques. In the absence of comparative studies, it is not possible from the epidemiologic data to issue recommendations for women at higher risk of unintended laparotomy. Our data provide an estimate of the magnitude of the increased risk, and leave the choice of surgical approach a matter for the individual clinician and patient to consider.

Decreasing incidence of invasive cervical cancer in young women

Joseph Chu, M.D., M.P.H., and Emily White, Ph.D.
Seattle, Washington

Although the overall incidence of invasive cervical cancer is decreasing, there is concern that the disease might be increasing in younger women. Analysis of data from the Cancer Surveillance System, a population-based cancer registry in western Washington, shows a decreasing incidence of cervical cancer in women of all ages. (AM J OBSTET GYNECOL 1987;157:1105-7.)

Key words: Cervical cancer, incidence in young women

Although the incidence of invasive cervical cancer has significantly decreased over the past decade in most Western countries, there is concern over the possible increase in occurrence and mortality in young women.[1-7] Possible reasons for this increased incidence and mortality in young women include increased sexual activity and infections, such as papillomavirus.

In 1978 Yule[1] noted that the number of deaths from cervical cancer in women under 35 years of age living in England and Wales had doubled between 1970 and 1976. This increase over time is quite different from the decrease seen in older women with cervical cancer. Similarly, there was an increase in the incidence of invasive cervical cancer among women aged 20 to 44 years between 1974 and 1980 in Queensland, Australia.[2]

Because of these observations in other geographic areas and the possible implications for cancer control, we examined the data from the Cancer Surveillance System of western Washington during two recent periods.

Methods

Since 1974 the Cancer Surveillance System has been part of the National Cancer Institute's population-based registry program (SEER). The Cancer Surveillance System collects incidence data on all newly diagnosed malignancies in the Puget Sound area from all hospitals, radiation therapist offices, and pathology laboratories. For our study, information for all cases of newly diagnosed invasive cervical cancer from 1974 to 1985 was abstracted from the registry. Annualized age-specific incidence rates were calculated for two 6-year periods, 1974 to 1979 and 1980 to 1985, on the basis of denominator estimates of the 1970 and 1980 census, and from population projections made by the U.S. Bureau of Census and the Washington State Office of Financial Management.

Results

Similar to other geographic areas, there was an overall decrease in the incidence of invasive cervical cancer, from 10.8/100,000 in 1974 to 1979 to 7.9/100,000 in 1980 to 1985 in western Washington (Table I). In ad-

dition to the decreasing incidence in the older age group, however, we also see a decreasing incidence in all 5-year age groups of younger women (those 39 years old or younger) in this area. It should be noted, however, that the percent decrease is less in women under 30 years of age.

Additional analyses were performed to investigate any possible changes in mortality in younger women. The stage at diagnosis and the survival of women with cervical cancer did not show any indication of increasing mortality in younger women.

Comment

Our finding of a decreasing incidence of invasive cervical cancer is contrary to "clinical impression." We do not believe our results or our geographic area are atypical, because our findings are very similar to those from other areas of the United States. Chow et al.[8] found a decreasing incidence of invasive cervical cancer in white women in Atlanta between 1975 and 1983 in women aged 25 to 29 and 30 to 34 years but not in women 15 to 24 years old. Peters et al.[9] also noted an annual decrease of 2.5% in invasive squamous cell carcinoma of the cervix in women <35 years old between 1972 and 1982 in Los Angeles. Analysis of data from the National Cancer Institute's 10 population-based SEER registries (approximately 10% of the U.S. population) shows a 16% decrease (from 5.8 to 4.9/100,000) in invasive squamous cancer of the cervix in women ages 15 to 39 years between 1974 to 1977 and 1982 to 1984.

Although the number of women diagnosed with invasive adenocarcinoma of the cervix is relatively small, the incidence of this disease in women <35 years old has increased.[9, 10] Schwartz and Weiss[10] noted over a twofold increase in women <35 years old between 1973 to 1975 and 1979 to 1982 (0.17 to 0.38/100,000) in the SEER program.

There are several explanations why our findings might differ from those of other studies.[1-6] All of the studies except one[4] that showed an increase in number of cases, incidence, or mortality among young women with cervical cancer are from outside the United States. The frequency of cytologic screening is quite different, and prevalence rates of the various risk factors might be different in these countries than the United States. Second, most of the reported increases in deaths and mortality rates in younger women with cervical cancer occurred in the 1960s and 1970s. Our registry began in 1974; thus it is possible that any increase before the beginning of our registry was missed.

Other factors might impair our ability to determine the incidence of invasive cervical cancer. First, the possibility that cases of invasive cervical cancer are not being ascertained is small. Case ascertainment is conducted through active search in multiple souces of data. The Cancer Surveillance System sends trained abstractors to all hospitals and radiation facilities to review hospital disease and operation indices and pathology reports. In addition, death certificates are checked. Second, if the pathologic criteria for diagnosing invasive cervical cancer had changed during the study period, it would be possible to find an artificial decrease. However, there has not been any change in the pathologic criteria for invasive cervical cancer during this time period. Third, if there were intensive screening of

young women, perhaps fewer women ever reach invasive cancer but instead are diagnosed with preinvasive stages such as dysplasia or carcinoma in situ. Consistent with this is the high rate of carcinoma in situ in our area. However, time trends of carcinoma in situ in most 5-year age groups in our area show decreases similar to those of invasive cancer (Table I). This decrease needs to be viewed with some caution, because it is likely that many cases recently diagnosed and treated have had all their care as outpatients and therefore may have not been ascertained. The findings of declining rates of carcinoma in situ have also been observed in Atlanta[8] and in Los Angeles.[9] Unfortunately, we do not know whether the incidence of less severe dysplasias (cervical intraepithelial neoplasia I and II) is increasing or decreasing, because the Cancer Surveillance System does not collect this information.

Our results, as well as those from other area-wide registries in the United States, do not support the clinical impression or previously published studies from outside the United States that there is an increase in the overall incidence of invasive cervical cancer in young women. This does not mean that the actual number of cases of invasive cervical cancer in young women is decreasing, because there are now more young women in the population. Whether the incidence of invasive cervical cancer will increase with the observed increases in papillomavirus infections of the cervix needs to be closely followed.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Menstrual and reproductive factors and the risk of myocardial infarction in women under fifty-five years of age

Carlo La Vecchia, M.D., Adriano Decarli, Sc.D., Silvia Franceschi, M.D., Antonella Gentile, Ph.D., Eva Negri, Sc.D., and Fabio Parazzini, M.D.
Milan, Italy

The relationship between menstrual and reproductive factors and subsequent risk of coronary heart disease was investigated in a hospital-based case-control study of 202 women with acute myocardial infarction and 374 control subjects admitted for a wide spectrum of acute conditions unrelated to any of the established risk factors for ischemic heart disease. No consistent association was observed with age at menarche or menopausal status, but women with a lifelong irregular menstrual cycle pattern were at significantly elevated risk of myocardial infarction (relative risk = 1.8, 95% confidence interval = 1.1 to 2.9). No clear trend in risk was evident with the number of livebirths, miscarriages, or induced abortions. However, women whose first pregnancy or livebirth occurred before age 20 years showed elevated risks of subsequent myocardial infarction compared with nulliparous ones (relative risks = 2.3; 95% confidence interval = 1.1 to 4.9), and there was a significant trend of increasing risk with earlier first birth. These associations were evident in both younger and middle-age women and were not explained by allowance for several identified potential confounding factors. (Am J Obstet Gynecol 1987;157:1108-12.)

Key words: Myocardial infarction, menstrual and reproductive factors, pregnancy

Evidence indicates that female hormones influence the risk of ischemic heart disease. The use of oral contraceptives increases the risk of myocardial infarction,[1] whereas it is still debated whether menopausal estrogen replacement treatment decreases the risk of cardiovascular disease.[2-4]

Fewer data are available on the potential role of endogenous hormones and their correlates, that is, menstrual and reproductive factors. Although it is known that the advantage that women have over men in the incidence of coronary heart disease and death is confined to the premenopausal years (postmenopausal female rates rise to become comparable with those for elderly men[5]), it is still uncertain whether early menopause increases the risk of myocardial infarction relative to premenopausal women of comparable age.[6-8] With regard to reproductive history, a study based on the Mayo Clinic record linkage system showed elevated risks in women whose first pregnancy was below age 25 years,[9] but the evidence was controversial in a large case-control study conducted in three geographic regions of North America.[8] In the present study, we have further considered the role of menstrual and reproductive factors in the risk of myocardial infarction with data from a case-control study conducted in Northern Italy where mortality rates from ischemic heart diseases are considerably lower than those in Northern European or American populations.[10]

Subjects and methods

Since January 1983, trained interviewers identified and questioned women below age 55 years admitted for acute myocardial infarction to the coronary care units of 30 hospitals in Lombardy and a few other areas in northern Italy (Turin, Genova, Verona, and Pisa). The general design of this investigation has already been described.[11] Briefly, a regular liaison with cooperating hospitals was maintained at approximately fortnightly intervals. Less than 2% of the case or control subjects approached for interview refused to participate.

A standard questionnaire was used to obtain information on sociodemographic factors, personal characteristics and habits (i.e., cigarette smoking, consumption of alcohol, coffee, and other methylxanthine-containing beverages), a few selected dietary items, menstrual and reproductive factors (i.e., age at menarche, menopausal status, lifelong menstrual pattern, number of livebirths and abortions, and age at first pregnancy and at first and last birth), and history of

lifetime use of oral contraceptives and female hormones for other indications.

The cases studied included 202 women under 55 years of age with a diagnosis of acute myocardial infarction according to the standard World Health Organization criteria. An additional 18 patients were considered unsuitable after review of the clinical records, chiefly because of recurrent infarction (n = 10) or uncertain diagnostic criteria (n = 8). The median age was 47 years, and 117 (58%) women were below age 50 years.

The control subjects were patients under age 55 years admitted to the same hospitals where cases had been identified for acute diseases other than cardiovascular, malignant, metabolic, hormonal, or gynecologic, which were diagnosed within the year before interview. Further exclusion was made of all primary diagnoses potentially related to cigarette smoking (e.g., peptic ulcer or abdominal hernia) or alcohol consumption (e.g., liver diseases). A total of 374 women 24 to 54 years old were interviewed; the median age was 45 years, and 267 (71%) were below age 50 years. Among them, 22% were admitted for traumatic conditions (mostly fractures or sprains), 22% had nontraumatic orthopedic disorders (mostly lower back pain and disc disorders), 25% were admitted for surgical conditions (including plastic surgery), and 31% had other illnesses, such as acute infections, skin, ear, nose and throat, or teeth disorders. The present analysis is based on data collected before February 1986.

Data analysis. Since cases were older than the comparison group, relative risk estimates (together with their 95% approximate confidence intervals)[12] were derived from data stratified for quinquennia of age by means of the usual Mantel-Haenszel procedure.[13] The significance of the linear trends in risk, where appropriate, was assessed with the test described by Mantel.[14] The potential confounding effect of several factors (geographic area, marital status, education, social class, cigarette smoking, alcohol and coffee consumption, diabetes, hypertension, obesity, hyperlipidemia, family history of ischemic heart disease, oral contraceptive and other female hormone use) was controlled for by means of stratification and the Mantel-Haenszel procedure.[13] Second, identified potential distorting factors were simultaneously controlled for by multiple logistic regression, fitted by the method of maximum likelihood.[12] Included in the regression equations, in addition to the menstrual and reproductive factors considered in this article, were terms for age, geographic area, marital status, education, social class, cigarette smoking, alcohol consumption, diabetes, hypertension, obesity, hyperlipidemia, family history of ischemic heart disease, and oral contraceptive and other female hormone use. Relative risk estimates from multiple logistic models were not materially different from the age-adjusted Mantel-Haenszel estimates, and only the latter are presented in the tables.

sociation with the risk of myocardial infarction is shown in Table I. Women with myocardial infarction more frequently were smokers and reported a history of diabetes, hypertension, hyperlipidemia, and a family history of coronary heart disease.

In Table II the relationship between selected menstrual characteristics and the risk of myocardial infarction is considered. Compared with women whose menarche occurred younger than 12 years, those with later menarche showed a reduced risk of infarction. However, there was no tendency for the risk to decrease with increasing age at menarche. Women with lifelong menstrual irregularities (simply defined as frequent occurrence of menstrual-like episodes less than 21 or more than 35 days apart) were at significantly elevated risk (relative risk = 1.8, 95% confidence interval = 1.1 to 2.9). In contrast, when age was allowed for, no significant relationship was evident between menopausal status and myocardial infarction risk. Allowance for major identified potential distorting factors by means of multiple logistic regression did not materially modify any of these estimates (i.e., multivariate relative risk for irregular menstrual cycle pattern = 2.1, 95% confidence interval = 1.2 to 3.3).

There was no consistent pattern of risk according to the number of livebirths, since the point estimate was above unity for women with one or two children and below unity for those with three or more births compared with nulliparas (Table III). Likewise, there was no relationship between infarction risk and the number of miscarriages or induced abortions (Table III).

Relative to women who had never been pregnant, the risk was significantly elevated (relative risk = 2.3, 95% confidence interval = 1.1 to 4.9) for those whose first pregnancy was below age 20 years, and the point estimate was above unity, although not significantly (relative risk = 1.5), for those women whose first pregnancy occurred above age 20 years (Table IV). The pattern of risk was similar with regard to age at first livebirth, and a significant trend of increasing risk with younger age at first livebirth was evident (Table IV). The relationship between early first birth was independent from the major identified potential distorting factors, since the multivariate relative risks were not materially different from the age-adjusted ones (relative risk for women before 20 years old at the first birth = 2.4 and 1.4 for those aged 20 to 24 years).

Likewise, the risk of myocardial infarction was significantly elevated (relative risk = 2.1) in women whose last birth occurred below age 25 years. However, the data are insufficient to allow separate analysis of the effects (and the interactions) of parity and age at first and last birth, which are, of course, strongly correlated.

The influence of early births on subsequent myocar-

dial infarction risk was long lasting, since the risk estimates were above unity for middle-aged (45 to 54 year) women, as well as for younger ones.

Comment

The findings of the present study indicate that several aspects of menstrual and reproductive history are related to the subsequent risk of acute myocardial infarction in younger and middle-aged women. The relative risk was significantly elevated for women with frequent irregularities in menstrual cycle and those with earliers pregnancies or births. No consistent association was evident for age at menarche, menopausal status, parity, and number of abortions.

It is unlikely that the present findings are largely influenced by obvious bias. The control subjects were admitted for a wide spectrum of acute conditions requiring hospital treatment apparently unrelated to menstrual or reproductive events, and the participation rate was almost complete. Several variables considered (parity, age at first birth, or menopausal status) should not be influenced by recall or information bias, and also for variables whose recall may not be totally reliable (i.e., age at menarche or menstrual cycle pattern), there is little support for different recall by cases and control subjects having any considerable impact on the risk estimates. The potential influence of menstrual and reproductive factors on myocardial infarction risk, in fact, was not known to the interviewers and probably not to most patients either, and the major attention in this study was on the effects of other risk factors, such as exogenous female hormones or smoking.[11]

With regard to confounding, the main findings of this study were not materially influenced by allowance for several identified potential distorting factors, including sociodemographic indicators and the major risk factors for myocardial infarction.

Thus this study confirms the indication of a case-control study based on 169 incidences of coronary heart disease (angina, myocardial infarction, and sudden unexpected death) in women under age 60 years from Rochester, Minnesota, during 1960 to 1979, which showed a relative risk of 1.9 for women whose age at first pregnancy was under 20 years and 1.8 for those 20 to 24 years compared with never pregnant women and those with later first pregnancy.[9] The results of another large North American case-control study were more controversial and not statistically significant, although the point estimates for women whose first pregnancy was below age 25 years were also above unity in that study.[8]

A second interesting finding of this study was the elevated risk among women with lifelong irregular menstrual cycle pattern. Although the rather crude definition used for "menstrual irregularity" does not allow precise definition of the biologic correlates of this finding, it is likely that women with menstrual irregularities have more frequent anovular cycles and several steroid hormone imbalances (i.e., hyperandrogenemia). It is, however, still difficult to reconcile in unifying and widely accepted hormonal correlates the various findings of the present study, including the absence of association with menopausal status (which is in agreement with some but not all previous studies).[6-8] Likewise, other pathogenetic hypotheses put forward to explain the lower cardiovascular mortality rates in women based, for instance, on the suggestion that menses may provide a mechanism for the elimination of blood-borne factors that participate in atherogenesis[15] are partly (i.e., positive association with irregular menses) but not totally (i.e., absence of association with age at menopause) consistent with the findings of the present study.

The influence of the major risk factors in the present

study (irregular menstrual pattern and age at first pregnancy or birth) was still evident in middle-aged women, that is, after an interval of several years or decades. This suggests that these factors may influence the subsequent risk of myocardial infarction even after a considerable time, as previously indicated from data on the discontinuation of oral contraceptive use.[16]

The negative relationship between age at first pregnancy or birth and the risk of ischemic heart disease, if confirmed, would have important public health implications, particularly if a similar relationship is not restricted to younger and middle-aged women analyzed in the present and previous[8, 9] work but also applies to older age groups in whom there is a substantially greater incidence of coronary events.[5, 10] Therefore it appears that the age at which a woman bears her first child is an important correlate of the subsequent history of several important diseases in terms of either direct (i.e., increased risk of breast cancer with increasing age at first livebirth)[17] or, possibly, inverse association (i.e., decreased risk of ischemic heart disease with older age at first livebirth).

Data processing and analysis were performed at the computing facilities of the Inter-University Consortium of Lombardy for Automatic Data Processing (CILEA).

The "breakfast tolerance test": Screening for gestational diabetes with a standardized mixed nutrient meal

Donald R. Coustan, M.D., John A. Widness, M.D., Marshall W. Carpenter, M.D., Lee Rotondo, R.N., and Doreen Chin Pratt, R.D.

Providence, Rhode Island

In a group of 50 presumed normal pregnant women and 20 known gestational diabetic women, all in the early third trimester, the function of a standard 50 gm, 1-hour screening test for gestational diabetes was compared with that of a plasma glucose level determined 1 hour after the ingestion of a standard 600 kcal mixed nutrient breakfast (breakfast tolerance test). The mean plus 2 SD for the breakfast tolerance test was 120 mg/dl. If this were used as the threshold for a screening test, 75% of cases of gestational diabetes would be identified (sensitivity), while 94% of normal pregnant women would be excluded (specificity). A threshold of 100 mg/dl yields a sensitivity of 96% and a specificity of 74%. These results are compared with those for the standard 50 gm glucose challenge. (AM J OBSTET GYNECOL 1987;157:1113-7.)

Key words: Gestational diabetes, diabetes screening test in pregnancy, glucose challenge in pregnancy, carbohydrate metabolism in pregnancy

The Second International Workshop Conference on Gestational Diabetes[1] has recommended that all gravid women be screened with a 50 gm, 1-hour glucose challenge at approximately 26 weeks of gestation, in order to detect the presence of gestational diabetes. The 50 gm screening test has been investigated extensively, and much is known about the manner in which this test functions.[2-4] However, logistic and economic disadvantages to using a carbohydrate load for screening make it advantageous to use some other type of screening test. Some investigators have explored the validity of a random glucose value, evaluated with[5] or without[6] reference to the interval since the last meal. Unfortunately, the content of the last meal was unknown in the former study,[5] and only 2.5% of the subjects had an oral glucose tolerance test, a number insufficient to determine the validity of the thresholds used. In addition, the criterion used in the above study for abnormality on the glucose tolerance test has not been validated for pregnancy. In the latter study,[6] only 48% of subjects with "impaired glucose tolerance in pregnancy" were detected by the random glucose screen. Nineteen percent had normal random values but underwent oral glucose tolerance tests because of historical risk factors and 33% did not have the random glucose screen. The authors recommended the random glucose determination as an adjunct to historical risk factors in choosing patients for glucose tolerance testing.

It is known that when carbohydrate is consumed with other nutrients, as in a mixed meal, the glycemic excursion is altered from that induced by an isocaloric pure carbohydrate load.[7] Thus it would be expected that the content of a recently ingested meal would influence the glucose level observed. The present investigation is designed to explore the function of a screening test for gestational diabetes based on the plasma glucose level observed 1 hour after the ingestion of a standardized mixed nutrient breakfast.

Subjects and methods

The subjects of this study include the same 70 pregnant individuals previously described in an investigation of the influence of fasting versus fed state on the 50 gm, 1-hour screening test.[4] Fifty were presumed normal women about to undergo screening for gestational diabetes, and an additional 20 had already been diagnosed as having gestational diabetes by the criteria of O'Sullivan and Mahan[8] as modified by Carpenter and Coustan.[3] Both groups of subjects were recruited from private obstetricians' offices and clinics, affiliated with the Women and Infants' Hospital of Rhode Island. Subjects were between 25 and 33 weeks of gestation at the time of the study; those with known gestational diabetes were approximately 3.5 weeks more advanced in gestation than presumed normal subjects, because they had already undergone the routine 50 gm, 1-hour

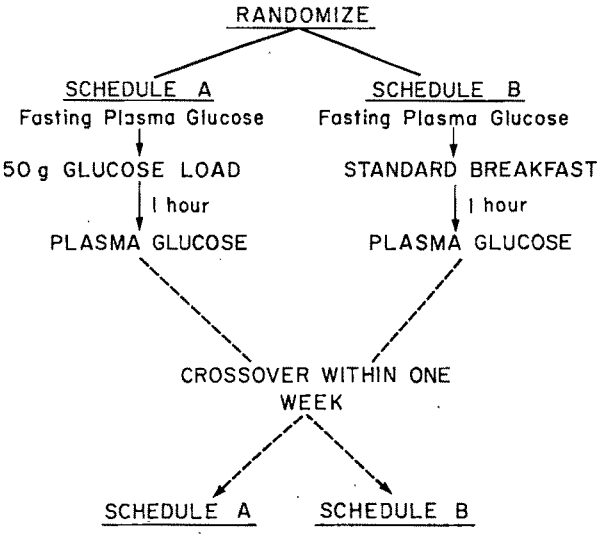

Fig. 1. Protocol for breakfast tolerance test.

screening test and the full 3-hour oral glucose tolerance test in the course of identification of the carbohydrate intolerance. Women with gestational diabetes were studied before starting on their dietary regimen. No patient was receiving insulin at the time of study. Demographic data describing these 70 individuals are presented in Table I.

The experimental protocol was approved by the Research and Human Subjects Committee of the Women and Infants Hospital of Rhode Island. All subjects fasted overnight before reporting for study. Twenty-four–hour dietary recall forms revealed that all subjects had ingested a minimum of 200 gm of carbohydrate on the day before the study. By means of a table of random numbers, the subjects were assigned one of two test schedules (Fig. 1). For schedule A, a sample for determination of the fasting plasma glucose level was first drawn, and subjects then drank a 50 gm oral glucose load (Limeondex, Curtin Matheson Scientific, Inc., Houston, Texas) over a period of 5 minutes. Plasma glucose was again measured 1 hour later. For schedule B, the subjects also had a sample drawn for determination of the fasting plasma glucose level but then consumed a standard mixed breakfast, consisting of approximately 600 kcal (Table II). One hour after completion of the mixed meal, a plasma glucose level was determined. As part of the previously published protocol,[4] the 50 gm glucose load was next administered, and a plasma glucose level was again obtained 1 hour later. Within 1 week, each subject was retested under the opposite conditions of the original test. The 50 presumed normal subjects and the 20 with gestational diabetes all completed the same protocol but were considered as two separate groups for purposes of randomization.

Blood samples were collected on ice in heparinized tubes and centrifuged within 1 hour. The plasma glucose level was determined by the glucose oxidase method (Yellow Springs Instrument Co., Yellow Springs, Ohio).

Presumed normal subjects were evaluated with a 3-hour, 100 gm oral glucose tolerance test if either 50 gm screening test value exceeded or equaled 130 mg/dl. The criteria of O'Sullivan and Mahan,[8] as modified for plasma and glucose oxidase,[3] were used as the diagnostic standard for gestational diabetes. All subjects with known gestational diabetes had previously been diagnosed with such a test, and oral glucose tolerance tests were not repeated in this group.

Mean values were compared with the two-tailed *t* test.

Results

Among the 50 presumed normal subjects, 24 underwent a 100 gm, 3-hour oral glucose tolerance test because one or both of the 50 gm screening tests met or exceeded 130 mg/dl. Among these 24, four met the criteria for gestational diabetes. It should be noted that all subjects whose 1-hour postbreakfast plasma glucose level was ≥100 mg/dl underwent a 3-hour glucose tolerance test, as all had one or both 50 gm, 1-hour screening test values equal to or exceeding 130 mg/dl.

Among the 46 confirmed normal subjects, the mean (±SD) plasma glucose level 1 hour after the test meal was 85.6 ± 17 mg/dl (Table III). Thus the mean + 2 SD was 119.6 mg/dl. The postmeal glucose levels of two of the presumed normal subjects with gestational diabetes exceeded 120 mg/dl, but those of the other two did not (100 and 101 mg/dl). There were three confirmed normal subjects whose postmeal plasma glucose value exceeded this threshold, and all three had elevated 50 gm, 1-hour screening test values but normal 100 gm, 3-hour glucose tolerance tests.

Sixteen of the 20 subjects with known gestational diabetes exhibited a 1-hour postmeal plasma glucose level ≥120 mg/dl, while four did not (87, 106, 111, and 114 mg/dl). The 20 known gestational diabetic individuals were combined with the four cases of gestational diabetes diagnosed among the 50 presumed normal individuals in order to calculate sensitivity estimates. Thus, with a threshold of ≥120 mg/dl, the sensitivity of this test was 75% and the specificity 94%. As shown in Fig. 2, lowering the threshold to 100 mg/dl increases the sensitivity of the test to 96% but decreases the specificity to 74%.

In order to quantitate the degree of glucose intolerance in individual subjects, the sum of the amount by which the two most abnormal oral glucose tolerance test values exceeded the upper limits of normal[9] was calculated (Δ glucose tolerance test value). The mean Δ glucose tolerance test value for the 20 known ges-

†Family history of diabetes, previous macrosomic baby (>9 pounds), poor obstetric history.

tational diabetic patients in this study was 51.4 ± 47.0 mg/dl, and the median was 30 mg/dl. The six cases not detected by the postmeal plasma glucose determination at a threshold of 120 mg/dl had a mean Δ glucose tolerance test of 20.7 mg/dl (range 11 to 39) and thus, as a group, had mildly abnormal glucose tolerance test results.

Comment

In the present study, the plasma glucose level 1 hour after a standard mixed-nutrient breakfast was evaluated as a screening test for gestational diabetes. Because of patient sampling methods, positive and negative predictive accuracy cannot be evaluated. Sensitivity (the proportion of individuals with the disease who are correctly identified by the test) and specificity (the proportion of individuals free of the disease who are correctly excluded by the test) can be assessed, however, because these parameters are relatively unaffected by disease prevalence.

The receiver operating characteristic curve (Fig. 2) is a convenient way to express the function of a screening test.[10] In this curve, sensitivity is plotted against (1 − specificity), so that the reader can see at a glance how much sensitivity is gained with a given decrease in the test threshold and how much specificity is lost in the process. Test sensitivity increases from 75% at a threshold of ≥120 mg/dl to 96% at ≥100 mg/dl. As with other screening tests, the threshold is chosen to maximize test sensitivity while maintaining good test

SD	16.9	21.8

df = 68; t = 8.22; $p < 0.00001$ (two-tailed *t* test).

specificity. The "breakpoint" of the receiver operating characteristic curve is that value at which the slope of increasing sensitivity falls, thus signifying a falloff in specificity without significant further gain in sensitivity.

The receiver operating characteristic curve for the breakfast tolerance test is compared with those for the 50 gm, 1-hour screening test administered in the fasting and fed states (Fig. 2). The "breakpoint" of the receiver operating characteristic curve for the breakfast tolerance test (100 mg/dl) is less discrete than that of the 50 gm, 1-hour screen in the fasting state (140 mg/dl) but more discrete than that of the 50 gm, 1-hour screen in the fed state (140 or 130 mg/dl). Thus the breakfast tolerance test functions slightly less efficiently than the 50 gm, 1-hour screen given to fasted subjects but more efficiently than the 50 gm, 1-hour screen in fed subjects.

Previous studies have suggested using a random plasma or whole-blood glucose determination as a screening test for gestational diabetes. Stangenberg et al.[6] (1985) described 6969 random capillary blood glucose measurements among 1500 pregnant women, reporting a mean of 83 mg/dl and a 95% upper confidence limit of 114 mg/dl. With a threshold of 116 mg/dl, 174 of the women had positive screening results on at least one occasion. Ten (0.7%) had abnormal carbohydrate metabolism by nonpregnancy glucose tolerance test standards. An additional four cases of gestational diabetes were diagnosed on the basis of a glucose tolerance test performed because of clinical suspicion, despite a "normal" random glucose measurement. Thus the sensitivity of this repetitive random capillary blood glucose screening test is, at best, 71%. It might be even lower, since 86.4% of the 1500 individuals had no test other than the random glucose determinations, and there is no information as to how many cases of gestational diabetes might have been missed by the screening test.

In the study of Lind and Anderson[5] (1984), 2403 patients had a venous plasma glucose determination between 28 and 32 weeks' gestation. On the basis of the patients' reports of the time of last meal ingestion, the results were divided into those from individuals who had eaten within 2 hours of sampling and those from individuals who has last eaten more than 2 hours before sampling. For those who had eaten within 2 hours, the mean plasma glucose level was 79 ± 13 mg/dl, and the 99% cutoff limit was 109 mg/dl. For those who had last eaten more than 2 hours before sampling, the mean was 73 ± 11 mg/dl and the 99% cutoff was 100 mg/dl. In 38 (1.4%) of the subjects the random glucose concentration exceeded (or nearly exceeded) the 99% cutoff, and a 75 gm oral glucose tolerance test was performed. Two of the 38 subjects had diabetes according to the World Health Organization criteria, and 11 had impaired glucose tolerance during pregnancy. Another 21 patients with normal random glucose screening tests underwent oral glucose tolerance testing for various clinical and historical indications. Three had impaired glucose tolerance. The low yield of gestational diabetes (0.25%) is about one tenth of that reported in most series that used other well-documented criteria and suggests that the morbidity associated with gestational diabetes would not be adequately predicted with this test. In fact, only 59 of the subjects (2.5%) had any testing other than the random capillary glucose determinations to look for gestational diabetes. Those authors assume that all of the 97.5% of patients not subjected to further testing would have had normal results had glucose tolerance tests been performed.

Recently, Mortensen et al.[11] investigated the use of the fasting whole-blood glucose level as a screening test for gestational diabetes in a population of 2448 pregnant women. A threshold of 73 mg/dl exceeded on two occasions prompted performance of a standard oral glucose tolerance test. Unfortunately, only patients with historical risk factors or glycosuria (7.8% of their population) were screened with fasting whole-blood glucose determinations. Although a control group of 54 nonscreened patients was tested with an oral glucose tolerance test at 28 weeks' gestation, the fact that none were diabetic does not imply that the incidence of gestational diabetes was negligible in the remaining 2394 untested patients, since the protocol described identified gestational diabetes in only 0.98% of the population.

The possible use of a fasting or random circulating glucose determination to detect gestational diabetes has not been tested in any substantial population, since screening tests must be validated by some confirmatory test (either the standard diagnostic test or some other standard screening test whose functions are already known) performed on the entire screened population. In the above three studies confirmatory testing was performed in only an extremely limited proportion of the screened population. The meal study reported herein was performed with the usual 50 gm, 1-hour screening test twice (once in the fed state and once in the fasting state) on all subjects screened. Since those subjects with 50 gm screening test values below 130 mg/dl on two occasions are extremely unlikely to have gestational di-

abetes,[3] the standard 3-hour, 100 gm oral glucose tolerance test was performed only in those patients with abnormal screens.

The values determined in the present study for plasma glucose 1 hour after a standard mixed-nutrient breakfast are similar to those in other reports in which this determination was not proposed as a screening test. Gillmer et al.[12] investigated glycemic excursions after a mixed breakfast containing 40 gm of carbohydrate (but an unreported amount of other nutrients) in 24 normal and 13 "chemical diabetic" women during the third trimester. They reported mean plasma glucose values of approximately 5 ± .5 mmol/L (89 ± 9 mg/dl) 1 hour after this meal among the normal individuals and approximately 6.2 ± 1.5 mmol/L (110 ± 27 mg/dl) among the "chemical diabetic" women. Cheney et al.[13] administered a 400 kcal breakfast (39 gm carbohydrate, 17 gm protein, 20 gm fat) to six normal, 23 lean gestational diabetic, and 12 obese gestational diabetic women at 35 weeks of pregnancy. The six normal women manifested a mean (±SE) plasma glucose level of 100 ± 5 mg/dl 1 hour after the breakfast. The lean gestational diabetic subjects in the study of Cheney et al. manifested a mean 1-hour plasma glucose level of approximately 125 ± 5 (SEM) mg/dl, similar to the 126 ± 21 (SD) mg/dl value obtained in our 19 nonobese gestational diabetic subjects. The obese gestational diabetic women in the study of Cheney et al. manifested a mean 1-hour plasma glucose level of approximately 150 ± 8 (SEM) mg/dl, somewhat higher than the 139 ± 24 (SD) mg/dl in our five obese gestational diabetic subjects.

The present study illustrates that the use of a standard mixed-nutrient meal as the provocative test for gestational diabetes screening may be as efficient as the use of a pure carbohydrate load, provided that the standard meal is one with a predictable effect on plasma glucose. This raises the possibility that some other standard oral challenge, which is palatable and prepackaged or easily measured and prepared, may be more readily administered, particularly in circumstances of limited financial resources.

Gestational diabetes: Maternal response to diet and insulin therapy as reflected by glycosylated hemoglobin concentration

Arnold S. Grandis, M.D., Ph.D., Mary Ann Morris, M.D., and Jean C. Litton, R.N., B.S.
Durham, North Carolina

To assess the effects of diet and insulin therapy on pregnancy complicated by gestational diabetes, glycosylated hemoglobin concentration was determined longitudinally in 32 women. Diet was instituted when a diagnosis of gestational diabetes was made and was supplemented with insulin for fasting hyperglycemia. At initial presentation, glycosylated hemoglobin concentration was increased in the 18 women who required insulin compared with the 14 women managed by diet alone (7.1% ± 0.2% versus 6.2% ± 0.2%, mean ± SEM, $p < 0.01$). Diet had no effect on glycosylated hemoglobin concentration that remained elevated to 6.1% ± 0.3% compared with the glycosylated hemoglobin concentration of 5.6% ± 0.2% for pregnant nondiabetic women ($p < 0.01$). Insulin resulted in a decrease in glycosylated hemoglobin concentration within 3 to 5 weeks ($p < 0.05$). After 7 to 9 weeks of insulin and diet, the glycosylated hemoglobin concentration in women with fasting hyperglycemia was the same as the glycosylated hemoglobin concentration in women who were managed by diet alone. (AM J OBSTET GYNECOL 1987;157:1118-21.)

Key words: Gestational diabetes, glycosylated hemoglobin concentration, diet and insulin therapy

Gestational diabetes, a frequent complication of pregnancy with an incidence of 1.6% to 3.0%, is associated with fetal macrosomia, as well as increased maternal morbidity and perinatal morbidity and death.[1, 2] In addition, there may be long-term sequelae of the abnormal maternal metabolism associated with gestational diabetes on both the mother and the developing fetus.[3-5]

The standard therapy for gestational diabetes is dietary counseling supplemented with insulin therapy if the woman maintains repetitive fasting hyperglycemia. Although dietary therapy has been demonstrated to decrease perinatal death, a perinatal morbidity rate of 25% persisted in gestational diabetic women who maintained fasting euglycemia.[6] O'Sullivan,[7] Oppermann and Camerini-Davalos,[8] and Coustan and Imarah[9] have demonstrated that prophylactic insulin treatment of gestational diabetic women significantly reduced the incidence of fetal macrosomia and the associated operative delivery and birth trauma. The subsequent development of overt diabetes by these gestational diabetic women later in life was also reduced by insulin therapy.[3]

Estimates of diabetes control based on sporadic measurements of glucose in urine or blood do not provide the requisite precision for adequate assessment of the efficacy of dietary and insulin therapy. Glycosylated hemoglobin concentration has been demonstrated to reflect glycemic control during the past 4 to 8 weeks in both nonpregnant and pregnant diabetic women.[10, 11] Therefore the present study was designed to assess the effects of dietary and insulin therapy in pregnancy complicated by gestational diabetes by serial measurement of glycosylated hemoglobin concentration.

Methods

Thirty-two women who developed gestational diabetes were studied longitudinally throughout pregnancy between April 1983 and August 1985 at Duke University Medical Center. Informed consent was obtained from all study patients. Women in whom diabetes was present before pregnancy were excluded.

A 100 gm oral glucose tolerance test was performed if the plasma glucose concentration 1 hour after a 50 gm oral glucose load exceeded 134 mg/dl.[12] This screening test was performed routinely at the first prenatal visit and repeated (on nondiabetic women) after 26 weeks' gestation. Other indications for the oral glucose tolerance test included excessive weight gain, fetal macrosomia, and polyhydramnios. Gestational diabetes was diagnosed by the criteria of the National Diabetes Data Group.[13]

When gestational diabetes was diagnosed, a registered dietician provided dietary instruction based on the American Diabetes Association principles of nutri-

tion.[14] Daily caloric recommendations were approximately 35 kcal/kg ideal body weight. Repeat dietary counseling was provided if excessive weight gain, fetal macrosomia, or polyhydramnios developed.

Insulin therapy was begun if the fasting plasma glucose concentration exceeded 104 mg/dl two or more times within a 1- to 2-week interval. Insulin therapy consisted of a split/mixed regimen of regular and NPH Humulin insulin (Eli Lilly) with both morning and afternoon administration. The women receiving insulin therapy practiced home blood glucose monitoring (Ames Glucometer) at least two to four times daily to determine appropriate insulin adjustments.

Eighteen of the 32 gestational diabetic women required insulin therapy. These women who required insulin were similar in age and incidence of prior pregnancy loss and chronic hypertension when compared with the diet-controlled group (Table I). Gestational age at the time of enrollment into the study was the same for the two study groups. Although overall weight gain during gestation was similar for the two study groups, the incidence of obesity (greater than 20% above ideal body weight) was significantly higher for the women who received insulin therapy ($p < 0.02$). None of these 18 women required insulin therapy after the completion of their pregnancy.

Glycosylated hemoglobin concentration was determined at 2- to 4-week intervals after enrollment in the study and at the 4- to 6-week postpartum visit. Glycosylated hemoglobin concentration was measured by affinity chromatography with m-amino-phenylboronic acid as previously described.[15] Statistical comparisons were performed by use of the Student *t* test or Fisher's exact test.

Results

The glycosylated hemoglobin concentration at initial presentation of the women who required insulin for the management of fasting hyperglycemia was compared with the glycosylated hemoglobin concentration of the women who were managed by dietary therapy alone. The glycosylated hemoglobin concentration in the insulin-treated group was significantly increased over the group managed with dietary therapy alone, 7.1% ± 0.2% and 6.2% ± 0.2% (mean ± SEM), respectively ($p < 0.01$).

Four to 6 weeks postpartum, the glycosylated hemoglobin concentration was similarly increased in those women who required insulin therapy; it was 7.2% ± 0.4% and 6.1% ± 0.2% in the insulin and dietary treatment groups, respectively ($p < 0.01$).

The effects of therapy on glycosylated hemoglobin concentration in the women treated with dietary therapy alone are presented in Table II. The women in this group were enrolled at 20.1 ± 2.4 weeks' gestation, and dietary therapy instruction was performed at 23.1 ± 2.0 weeks. Throughout the remainder of gestation, there was no change in the glycosylated hemoglobin concentration, even after 11 to 13 weeks of conventional dietary therapy.

Table I. Clinical characteristics of the two study groups

Clinical characteristics	*Diet alone (n = 14)*	*Diet plus insulin (n = 18)*
Age (yr)	29.4 ± 0.9	31.9 ± 1.6
Prior pregnancy loss (%)	36	33
Chronic hypertension (%)	21	44
Weight gain (lb)	26.8 ± 3.7	26.1 ± 4.0
Obesity (%)	57	95*
Enrolled (wk)	20.1 ± 2.4	21.8 ± 1.5
Diet therapy (wk)	23.1 ± 2.0	22.1 ± 1.6
Insulin therapy (wk)	—	26.3 ± 1.6

Mean ± SEM.
*$p < 0.02$.

The effects of therapy on glycosylated hemoglobin concentration in women treated with dietary plus insulin therapy caused by repetitive fasting hyperglycemia are presented in Table III. The women in this group were enrolled at 21.8 ± 1.5 weeks' gestation. Dietary therapy instruction was performed at 22.1 ± 1.6 weeks, and insulin therapy was begun at 26.3 ± 1.6 weeks.

In this group requiring insulin therapy, the glycosylated hemoglobin concentration was not changed by dietary therapy alone. However, the glycosylated hemoglobin concentration of 7.3% ± 0.3% at initiation of insulin therapy significantly declined to 6.8% ± 0.2% after 3 to 5 weeks of insulin therapy ($p < 0.05$). The glycosylated hemoglobin concentration continued to decrease, and by 7 to 9 weeks of insulin therapy, the glycosylated hemoglobin concentration was down to 6.4% ± 0.3% ($p < 0.01$).

By the end of gestation, the glycosylated hemoglobin concentration of the diet alone and the diet plus insulin therapy groups was essentially the same, 6.1% ± 0.3% and 6.4% ± 0.3%, respectively. The incidence of a large for gestational age infant was also similar, 21% and 28% for the diet alone and diet plus insulin therapy groups, respectively. Likewise, the incidence of neonatal hyperbilirubinemia was similar for the two study groups, 30% and 27%, respectively. The neonatal plasma glucose concentrations at 1 hour of age were not significantly different at 39.1 ± 0.9 and 35.9 ± 2.2 mg/dl for the diet alone and diet plus insulin therapy groups, respectively.

Comment

The intent of conventional dietary and insulin therapy for gestational diabetes mellitus is the avoidance of maternal hyperglycemia. Maternal hyperglycemia is re-

lated to fetal macrosomia.[2, 16] Fetal macrosomia is associated with perinatal complications such as maternal morbidity, birth trauma, neonatal hypoglycemia, neonatal hyperbilirubinemia, and perinatal mortality.

Prior studies have demonstrated that women who develop gestational diabetes mellitus consistently have elevated glycosylated hemoglobin concentrations throughout gestation compared with women who have normal carbohydrate metabolism.[15] Recent work has further demonstrated that maternal glycosylated hemoglobin concentration, which is measured by affinity chromatography, correlates closely with maternal plasma glucose concentration.[11]

Although most women with gestational diabetes may be able to avoid fasting hyperglycemia with dietary therapy alone, maternal nonfasting hyperglycemia persists as demonstrated by the inability of dietary therapy to normalize the maternal glycosylated hemoglobin concentration. Based on a longitudinal study of glycosylated hemoglobin concentration in nondiabetic women throughout gestation, the glycosylated hemoglobin concentration reaches a plateau of 5.6% ± 0.2% during the third trimester.[15] However, as demonstrated by this study, gestational diabetic women managed with dietary therapy alone maintained a glycosylated hemoglobin level elevated to 6.1% ± 0.3% ($p < 0.01$).

Therefore the results of this study suggest that conventional dietary therapy alone is of limited benefit in the control of nonfasting hyperglycemia in pregnancy complicated by gestational diabetes. This inability of conventional dietary therapy to normalize the glycosylated hemoglobin concentration is consistent with the demonstration by Gabbe et al.[6] that although dietary therapy may avoid fasting hyperglycemia and unexplained intrauterine fetal demise, there still is a 25% incidence of neonatal morbidity.

Conventional management of gestational diabetes mellitus recommends insulin therapy for repetitive fasting hyperglycemia after appropriate dietary therapy has been used. The present study demonstrated that the women who develop fasting hyperglycemia have a higher glycosylated hemoglobin concentration (7.1% ± 0.2%) in early gestation than gestational diabetic women who maintain fasting euglycemia (6.2% ± 0.2%, $p < 0.01$).

In addition, when insulin therapy was used because of repetitive maternal fasting hyperglycemia, the maternal glycosylated hemoglobin concentration decreased from 7.3% ± 0.3% to 6.4% ± 0.3% ($p < 0.01$). Therefore after only 7 to 9 weeks of combined insulin and dietary therapy, the glycosylated hemoglobin concentration in women with fasting hyperglycemia was the same as the glycosylated hemoglobin concentration in gestational diabetic women who had been managed by conventional dietary therapy alone. This finding is consistent with prior studies that have suggested that prophylactic insulin treatment of all gestational diabetic women reduces the incidence of fetal macrosomia and the associated operative delivery and birth trauma.[7-9]

In conclusion, the conventional therapeutic stan-

dards for gestational diabetes are inadequate for the prevention of nonfasting hyperglycemia and associated maternal and neonatal morbidity. This study provides the rationale for a randomized study to determine whether perinatal outcome can be improved by normalization of the glycosylated hemoglobin concentration throughout gestation by either more intensive dietary monitoring or combined insulin and dietary therapy.

Preliminary observations on lactoferrin secretion in human vaginal mucus: Variation during the menstrual cycle, evidence of hormonal regulation, and implications for infection with *Neisseria gonorrhoeae*

Myron S. Cohen, M.D., Bradley E. Britigan, M.D.,* Martha French, B.S., and Karen Bean, B.S.

Chapel Hill, North Carolina

The concentration of the iron-binding protein lactoferrin was measured in vaginal mucus of women throughout the menstrual cycle. Lactoferrin is proposed to limit growth of mucosal pathogens such as *Neisseria gonorrhoeae*. Lactoferrin concentration in mucus was highest just after menses (62.9 to 218 μg/mg of protein) and lowest (3.8 to 11.4 μg/mg of protein) just before menses. Overall concentration of mucus protein showed no variation with menstrual cycle, and little lactoferrin was detectable in cell debris. Plasma lactoferrin did not show the variation seen in vaginal mucus. Because of the suggestion of hormonal influence on vaginal lactoferrin, its concentration was determined in women receiving oral contraceptive therapy. Mean lactoferrin concentration in women taking oral contraceptives was significantly lower than in the control group (never exceeding 19.8 μg/mg of protein) and showed no monthly variation. Vaginal lactoferrin appears to be under hormonal control. Variation in vaginal lactoferrin concentration may result in alterations in susceptibility to bacterial pathogens such as *Neisseriae gonorrhoeae*. (AM J OBSTET GYNECOL 1987;157:1122-5.)

Key words: Vaginal mucus, lactoferrin, *Neisseria gonorrhoeae*

Lactoferrin is a glycoprotein present in most secretions found at mucosal surfaces[1] and in secondary granules of polymorphonuclear neutrophils.[2] This protein may have a number of different functions,[3, 4] but its most striking feature is its high affinity for iron.[5] In this context, lactoferrin may play an important role in inflammation by removing free iron that otherwise might catalyze the formation of the hydroxyl radical[6] and by inhibiting growth of a variety of microorganisms that require iron for normal metabolism.[7] A direct bactericidal effect of lactoferrin has also been reported.[8]

The idea that lactoferrin might limit the growth of *Neisseria gonorrhoeae* has received particular attention because this pathogen is strictly limited to a human reservoir.[9] However, the relevance of this hypothesis is to a great extent dependent on the actual concentration of lactoferrin to which such organisms are exposed. In this article, we show that lactoferrin is found in remarkably high concentration in vaginal secretions with significant, reproducible variation during the menstrual cycle.

Methods

Vaginal mucus collection. Eight healthy female volunteers were recruited. Half the subjects used combination oral contraceptives including Orthonovum 1/50 (Ortho Pharmaceutical, Rantam, N.J.) and Lo/Ovral (Wyeth Pharmaceutical). Specimens were collected according to a protocol approved by the Human Subjects Committee of the University of North Carolina. Subjects were instructed to place a 5 by 5 cm surgical sponge (Lisco, Kendal Company Hospital Products, Boston, Mass.) into their vagina on the morning of collection. Sponges had a nonabsorbable surgical suture attached to facilitate removal. Sponges were left in place for 24 hours, removed by the subjects, and placed immediately inside a sterile 10 ml plastic syringe (BD, Becton Dickinson and Co., Rutherfordton, N.J.). Specimens were returned within 1 hour of collection or kept at 4° C until return was possible. The sponge in the syringe was compressed to mobilize absorbed secretions and aliquoted directly (0.1 ml fractions) into Eppendorf tubes that were centrifuged at 15,000 g for 15 minutes.

Supernatant and pellet material was aliquoted and frozen at −70° C.

Timing of collections was as follows: Subjects waited 2 full days after their menstrual blood flow ceased, after which samples were obtained on 2 consecutive days. Subjects then waited 3 days and two additional samples were collected. This pattern continued until eight samples were obtained or menses ensued. Specimens from different subjects were grouped so that they were within 1 day of each other in the menstrual cycle, and results are reported in terms of the day most strongly represented by the samples available.

Preparation of plasma. Plasma from healthy volunteers was collected according to this schedule. Plasma was separated from whole blood as previously described.[10]

Determination of lactoferrin by enzyme-linked immunosorbent assay. Lactoferrin concentration was determined by a peroxidase-based enzyme-linked immunosorbent assay procedure as previously described.[10] Briefly, the immunoglobulin fraction of rabbit antihuman lactoferrin (Cappel No. 0201-1092) was diluted to 10 μg/ml in carbonate-coating buffer, pH 9.6. The 96-well microtiter plates (NUNC-Inter Med immunoplate 1 96F) were coated with 0.1 ml/well of this antibody overnight at 4° C. Each well was washed four times with 0.35 ml phosphate-buffered saline solution/Tween 20. Washings were done with a NUNC-Immuno Wash 12 (NUNC-Inter Med, Denmark) or automated microplate washer (Model EL402, Bio-Tek Instruments, Burlington, Vt.). Control testing showed similar results with either washing procedure. Purified human milk lactoferrin (Sigma L-8010, Sigma Chemical, St. Louis, Mo.) was diluted in 1% bovine serum albumin/phosphate-buffered saline and used for standards, with concentrations ranging from 1.6 to 64 ng/ml. The standards or unknowns were added to the plates, 0.1 ml/well, and incubated at 37° C for 1 hour. The plates were washed four times with phosphate-buffered saline solution/Tween 20.

Peroxidase-conjugated rabbit antihuman lactoferrin (Cappel No. 3201-1092) substrate diluted in 25 ml of citric acid buffer, pH 5.0, 25 ml of distilled H_2O, 20 mg/ml of phenylene diamine (Sigma P3888), and 0.018 ml of 30% H_2O_2, was added to the wells. Additions were done in 5-second intervals with a total reaction time of 4 minutes. The reaction was stopped with 8N H_2SO_4 and immediately read on a Bio-Tek microplate autoreader (Model No. EL309) at 492 nm. To ensure that the assay did not measure transferrin, control experiments were conducted in which human transferrin (Sigma) was added to the enzyme-linked immunosorbent assay. Interference was noted only at milligram concentrations, whereas transferrin was not detected in vaginal mucus by rate nephelometry sensitive to 25 μg/ml.

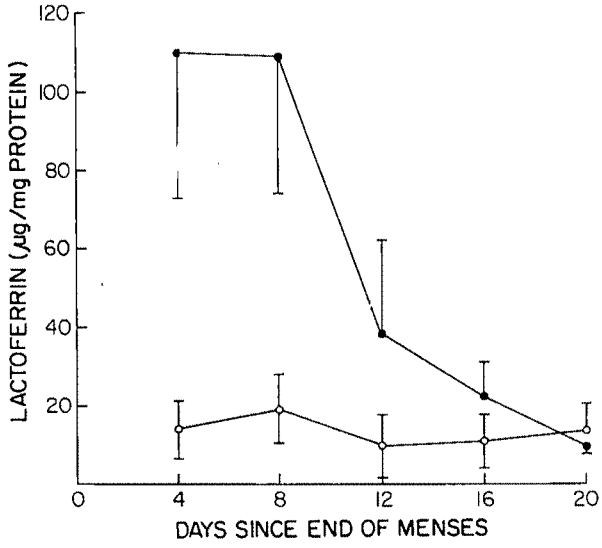

Fig. 1. Lactoferrin in the supernatant fluid of vaginal mucus (see Methods section) expressed per milligram of protein in the sample. Results are the mean of three separate donors in each group for whom adequate material was available for complete analysis in duplicate on two separate occasions. (o — o = Oral contraceptive pills; ● — ● = control.)

Results

Fig. 1 shows the mean concentration of lactoferrin in vaginal mucus in normal volunteers throughout their menstrual cycle. In women not receiving oral contraceptives, lactoferrin concentration was highest after menses, ranging from 62.9 to 218.0 μg/mg of protein, and was lowest just before the onset of menses, ranging from 3.87 to 11.4 μg/mg of protein. Because vaginal mucus protein was used as a denominator, we measured its variations throughout the menstrual cycle. As shown in Fig. 2, protein concentration did not vary widely during the menstrual cycle. We also examined the lactoferrin concentration of material (cell debris) pelleted out during the collection of vaginal mucus (see Methods section). This material was richer in protein (4 to 8 mg/ml of secretion), but the lactoferrin concentration did not exceed 7.3 μg/ml in any sample.

The source of lactoferrin in vaginal mucus is not known. It is possible that leakage from serum may play a role. As shown in Fig. 3, plasma lactoferrin ranged from 0.355 to 0.769 μg/ml during the menstrual cycle. Plasma lactoferrin concentration was highest just before or during menses, but the large variation seen in vaginal secretions was not observed.

Our results suggested that variation in vaginal lactoferrin was related to hormonal changes occurring

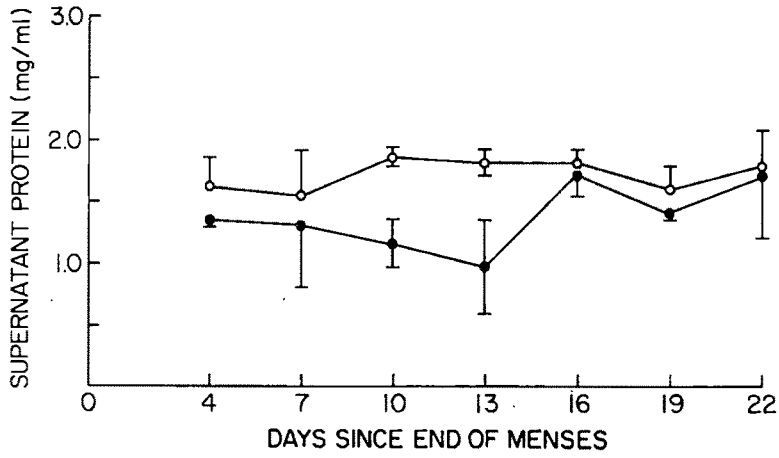

Fig. 2. Protein concentration in vaginal mucus during the menstrual cycle. Samples were examined as described in Fig. 1. (o—o = Oral contraceptive pills; •—• = control.)

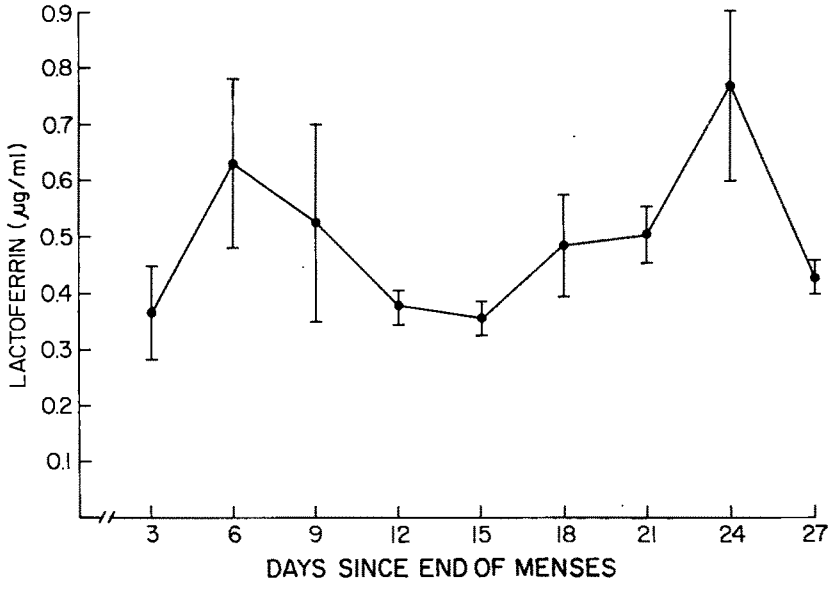

Fig. 3. The mean lactoferrin concentration in the plasma of three healthy volunteers. Samples were collected throughout the menstrual cycle and measured in duplicate.

during the menstrual cycle. To assess this hypothesis, we examined vaginal mucus secretion from women using oral contraceptives. As shown in Figs. 1 and 2, the mean lactoferrin concentration in women receiving oral contraceptive therapy was considerably lower than in the control group and did not exceed 19.8 µg/mg of mucus protein. The difference in lactoferrin secretion between control donors and donors receiving oral contraceptives was observed during most of the menstrual cycle (Fig. 1). Even more striking, lactoferrin concentration did not show monthly variation in women receiving oral contraceptive therapy (Fig. 1).

Comment

In this study we characterized lactoferrin secretion in the vaginal mucus of healthy volunteers. Lactoferrin was found predominantly in supernatant preparations free of cellular debris. Mean vaginal lactoferrin concentration in donors not receiving oral contraceptives ranged from 9 to 109 µg/mg of vaginal mucus protein, depending on the time of collection relative to menses. These concentrations of lactoferrin are consistent with an earlier report by Masson et al.,[1] in which lactoferrin was quantitated in "genital mucus" and was said to be between 0.5 and 1.0 mg/ml. This concentration of lactoferrin is greater than that found in most other secretions previously examined.[1]

Assays for detection of lactoferrin have received much attention.[10-12] Our assay was sensitive to nanogram concentrations of this protein and our results proved highly reproducible.[10] The concentrations of lactoferrin we detected in plasma were consistent with

the existing literature,[10-12] which further validated our assay. Because of the complex nature of vaginal mucus, we also performed "spiking" experiments in which known amounts of milk lactoferrin were added to vaginal mucus. Recovery in these experiments was 84% (n = 10, data not shown), so it seems likely that the lactoferrin values reported were accurate.

Lactoferrin concentration in vaginal mucus varied dramatically during the menstrual cycle and was lowest just before menses. Lactoferrin concentration was significantly reduced in women receiving oral contraceptives and failed to vary during the menstrual cycle. Earlier work has suggested hormonal effects on lactoferrin formation in other tissues: (1) Milk lactoferrin concentration decreases 4 days postpartum[13]; (2) neutrophil and serum lactoferrin are lower in women than men[11, 12]; (3) lactoferrin concentration is greater in the plasma of postmenopausal than premenopausal women[11]; and (4) lactoferrin staining in the endometrium is greater in the (later) secretory phase of the menstrual cycle.[14, 15]

The potential sources of lactoferrin in vaginal secretions include plasma (serum), neutrophils, and secretion by cervical or endometrial cells. The relative contribution of these sources remains unknown but given the concentration detected in vaginal mucus, it seems unlikely that plasma[10, 11] or polymorphonuclear neutrophils,[12] are of primary importance. The paradoxic increase in endometrial lactoferrin previously reported[14, 15] at a time when vaginal mucus lactoferrin is falling suggests that vaginal lactoferrin is derived from another source (e.g., endocervix[16]) that greater secretion from this tissue occurs early in the menstrual cycle, or that endometrial lactoferrin lost (shed) during menses remains in vaginal secretions after menses.

Given the amount of epidemiologic data used to explain the biology of gonococcal infection,[9] it seems warranted to speculate on how our findings might relate. Many organisms that produce disseminated gonococcal disease cannot use lactoferrin as an iron source.[9] Disseminated gonococcal infection frequently begins during menses.[9] At this time iron from other sources may reach the concentration required for the growth of these variants, overcoming the limitation imposed by lactoferrin. The effects of oral contraceptives (and concommitant lactoferrin suppression) on the biology of the vaginal flora remain to be determined.

Human chorionic gonadotropin, estriol, and testosterone changes in two pregnancies with hyperreactio luteinalis

Eberhard K. Muechler, M.D., Jeffrey Fichter, M.D., and John Zongrone, B.S.
Rochester, New York

A case of hyperreactio luteinalis is presented with measurements of human chorionic gonadotropin, total and free testosterone, and estriol throughout two term pregnancies. Ovulation induction with menotropins resulted in one spontaneous first-trimester abortion, one singleton term pregnancy, and 1 triplet pregnancy that converted to a singleton term pregnancy after spontaneous degeneration of two fetuses in the first trimester. During the first term pregnancy, levels of human chorionic gonadotropin peaked at 34 weeks of gestation (169,000 mIU/ml) and levels of total testosterone peaked at the same time (1777 ng/dl). Free testosterone (16.6 ng/dl) and estriol (10.8 ng/ml) reached their peak at 36 weeks of gestation. During the second term pregnancy, peak values of human chorionic gonadotropin (150,900 mIU/ml) and total testosterone (870 ng/dl) occurred at 10 and 5 weeks of gestation, respectively, before two fetuses of a triplet pregnancy degenerated. (AM J OBSTET GYNECOL 1987;157:1126-8.)

Key words: Hyperreactio luteinalis, testosterone, human chorionic gonadotropin, estriol, polycystic ovarian disease

Virilization during pregnancy may affect the mother alone or both mother and female fetus. Fetal virilization has been observed with androgen-producing tumors or with luteomas of pregnancy, but not with hyperreactio luteinalis. Maternal virilization occurs in 25% of cases with hyperreactio luteinalis and in 10% to 50% of all cases with luteoma of pregnancy.[1]

Reviews in the literature give only scant data on the underlying endocrine pathophysiology of hyperreactio luteinalis and luteoma of pregnancy. We had the opportunity to study a patient prospectively and longitudinally for several years from the time of diagnosis and treatment of anovulation and infertility to the completion of two term pregnancies. Observations of hormone measurements during this time are reported.

Case report

At the time of referral to the Reproductive Endocrine Unit, the patient was a 22-year-old Caucasian woman. She had normal breast and pubic hair development at 12 years of age. She subsequently experienced menarche at 13 years of age with irregular menstrual cycles every 1 to 3 months lasting 5 days. At 15 years of age, she was thin and muscular with facial acne and pigmented hair on her chin, upper lip, and cheeks. Laboratory data at that time revealed the following values: follicle-stimulating hormone (FSH), 7.6 mIU/ml (normal 5 to 25 mIU/ml); luteinizing hormone (LH), 28 mIU/ml (normal 4 to 30 mIU/ml); 17-ketosteroids, 10.6 mg/24 hr (normal 7 to 15 mg/24 hr); 17-hydroxycorticosteroids, 5.2 mg/24 hr (normal 2 to 11 mg/24 hr); and pregnanetriol, 3 mg/24 hr (normal 0 to 4 mg/24 hr). At the age of 22 years weight was 126 pounds, and height 5 feet 3 inches. The facial skin was oily with mild acne. Coarse, pigmented hair was present on chin, upper lip, cheeks, neck, chest, abdomen, and all extremities. Her voice had a low pitch. A slight recession of the temporal hair line was noted. On pelvic examination the glans of the clitoris measured 0.5 by 0.7 cm. Both ovaries were symmetrically enlarged to two to three times normal size. All other organs were normal as assessed by inspection and palpation. Ultrasound examination of the pelvis revealed enlarged, multicystic ovaries with no evidence of a tumor. Laboratory results showed levels of prolactin of 30 ng/ml (normal 0 to 35 ng/ml) and of serum testosterone of 188 ng/dl (normal 22 to 103 ng/dl). She was admitted to the Clinical Research Center for ovarian and adrenal stimulation and suppression and retrograde catheterization of the ovarian and adrenal veins combined with hormone analysis. Androgen levels of ovarian vein blood excluded the presence of an androgen-producing tumor: In the left ovarian vein the level of testosterone was 118 ng/dl and that of dihydrotestosterone was 67 ng/dl. In the right ovarian vein the testosterone level was 129 ng/dl and the dihydrotestosterone level was 97 ng/dl. Suppression of adrenocortical function with 2 mg of dexamethasone for 5 days resulted in a marked decrease of 17-hydroxycorticosteroids excretion in the urine and no change in urinary 17-ketosteroids, serum testosterone, dihydrotestosterone, estrone, and estradiol excretion. Ovarian stimulation with intramuscular injections of 5000 U human chorionic gonadotropin (hCG) for

Umbilical cord blood	61	726	0.48	35	154.5

*ND = Not detectable.

3 days in the presence of adrenocortical suppression with dexamethasone increased levels of testosterone from 93 to 220 ng/dl and of estradiol from 108 to 248 pg/ml without changing levels of dihydrotestosterone and estrone in peripheral blood. The rapid intravenous bolus injection of adrenocorticotropic hormone (0.25 mg cosyntropin) had no effect on peripheral serum levels of testosterone, dihydrotestosterone, estradiol, and estrone for 180 minutes. Serum estrone and estradiol levels were measured by radioimmunoassay after column fractionation. Estriol was determined by the Quantimune estriol radioimmunoassay (Biorad, Richmond, California). Total testosterone was determined by the Testosterone Test Set (Radioassay Systems Incorporated, Carson, California). Free testosterone was measured by the Coat-a-count Free Testosterone Radioimmunoassay (Diagnostic Products Corporation, Los Angeles, California). Testosterone and dihydrotestosterone were separated by column chromatography and analyzed by radioimmunoassay. Human chorionic gonadotropin was measured by the Tandem-R hCG, Immuno Radio Metric Assay (Hybritech Incorporated, San Diego, California). All other hormone determinations were carried out by standard measurements in the Clinical Chemistry Laboratory of Strong Memorial Hospital, Rochester, N.Y.

On the basis of the clinical findings and laboratory values of an LH:FSH ratio of 3.7:1 combined with high levels of serum and urinary androgens, a diagnosis of polycystic ovarian disease was made. Treatment with clomiphene citrate in increasing doses did not result in ovulation. The addition of prednisone to therapy was equally unsuccessful in stimulating ovulation. The patient then underwent ovulation induction with human menopausal gonadotropin–hCG for five treatment cycles. This resulted in a first-trimester miscarriage after the third treatment cycle and a viable, singleton pregnancy after the fifth cycle. During the first term pregnancy the patient's voice deepened slightly and an increase in skin oiliness was noted. Total and free testosterone, hCG, and estriol levels were measured in intervals throughout pregnancy, after delivery, and in umbilical cord blood (Table I). At 41 weeks of gestation labor was induced because of hypertension, and she was delivered of a normal male infant by cesarean section with a birth weight of 4280 gm. The placenta was

normal in weight and appearance. The ovaries were markedly enlarged, smooth, and multicystic, measuring 15 by 10 by 8 cm bilaterally. The appearance of the ovaries was consistent with the diagnosis of hyperreactio luteinalis. The infant required operation because of pyloric stenosis at 3 months of age and has developed normally until this time. One year after delivery the patient desired pregnancy again. Laparoscopy revealed symmetrically enlarged, polycystic ovaries. On microscopic examination an ovarian biopsy specimen was consistent with a diagnosis of polycystic ovarian disease.

An interval of 2½ years passed between delivery of the first term pregnancy and conception of the second term pregnancy we describe. After two treatment cycles of human menopausal gonodotropin–hCG therapy, she conceived a triplet pregnancy. During the first trimester of the triplet pregnancy we observed several episodes of vaginal spotting. Ultrasound examination at 11 and 13 weeks of gestation documented that these bleeding episodes coincided with the degeneration and disappearance of two fetuses. A single male fetus was carried to term and delivered by repeat cesarean section (birth weight 4000 gm). The ovaries were similar in appearance and size as during the first cesarean section. The results of hormone measurements for this last pregnancy are summarized in Table II.

Comment

This case report of hyperreactio luteinalis in a patient with polycystic ovarian disease describes hormone regulation before pregnancy and during pregnancy. The predisposition of polycystic ovarian disease to the development of hyperreactio luteinalis or luteoma of pregnancy is established by other case reports in the literature. In our case, as well as in others with luteoma or hyperreactio luteinalis, the abnormal condition of maternal virilization was repetitive in two consecutive pregnancies. Selective adrenal and ovarian vein catheterization with androgen and estrogen determinations in the venous effluent was consistent with values reported in ovarian vein blood of hirsute women or women with polycystic ovaries. Stimulation and suppression tests of ovarian and adrenal function were performed in our patient before conception.

Androgen, estrogen, and hCG determinations during pregnancy and in umbilical cord blood are the most important data of our report. From 10 to 22 gestational weeks the hCG values remained relatively constant during the first term pregnancy. This was followed by extremely low measurements of 50 mIU/ml at 26 weeks and a peak of 169,000 mIU/ml at 34 weeks of gestation. During her second term pregnancy, peak levels of hCG were measured at 10 and 15 weeks of gestation. This difference between both pregnancies may be explained by the fact that the large placental mass of her second pregnancy associated with triplets produced more hCG during the first trimester. After the degeneration of two triplets, the functional placental mass decreased to that of a continuing normal singleton pregnancy. No comparable results can be found in the literature, as only single hCG determinations at term have been reported in cases of hyperluteinization.

The observations for total testosterone differ for both term pregnancies in our patient. While maximal values of 13 to 17 times baseline were measured in the third trimester of her first term pregnancy, the maximal increase in total testosterone was noted at 5 to 10 weeks of gestation of her second term pregnancy. Both peaks of total testosterone secretion coincide with the peaks of hCG secretion. Similar observations of increases in total testosterone with hyperluteinization have been reported by several authors. However, free testosterone data are available in only one case report.[2] Measurements of total testosterone in cord blood were 2.8 and 7.26 ng/ml in both term pregnancies of our patient. This compares with values of 0.26 to 4.65 mg/ml reported by others. Free testosterone levels in cord blood have not been reported. It is therefore difficult to put our values of 0.12 and 0.4 ng/ml of free testosterone in cord blood into perspective. Our observations for serum estriol in both term pregnancies fall within the normal range and show only minor differences between the first and second term pregnancies. The variations between both pregnancies may be explained by secretory differences related to placental mass. In our patient maternal virilization is explained by the increase of total and free testosterone in the maternal circulation. Fetal virilization cannot be assessed in our patient because both pregnancies resulted in male infants. The measurements of free and total testosterone in cord blood of both pregnancies suggest that fetal virilization in female offspring is possible with hyperreactio luteinalis.

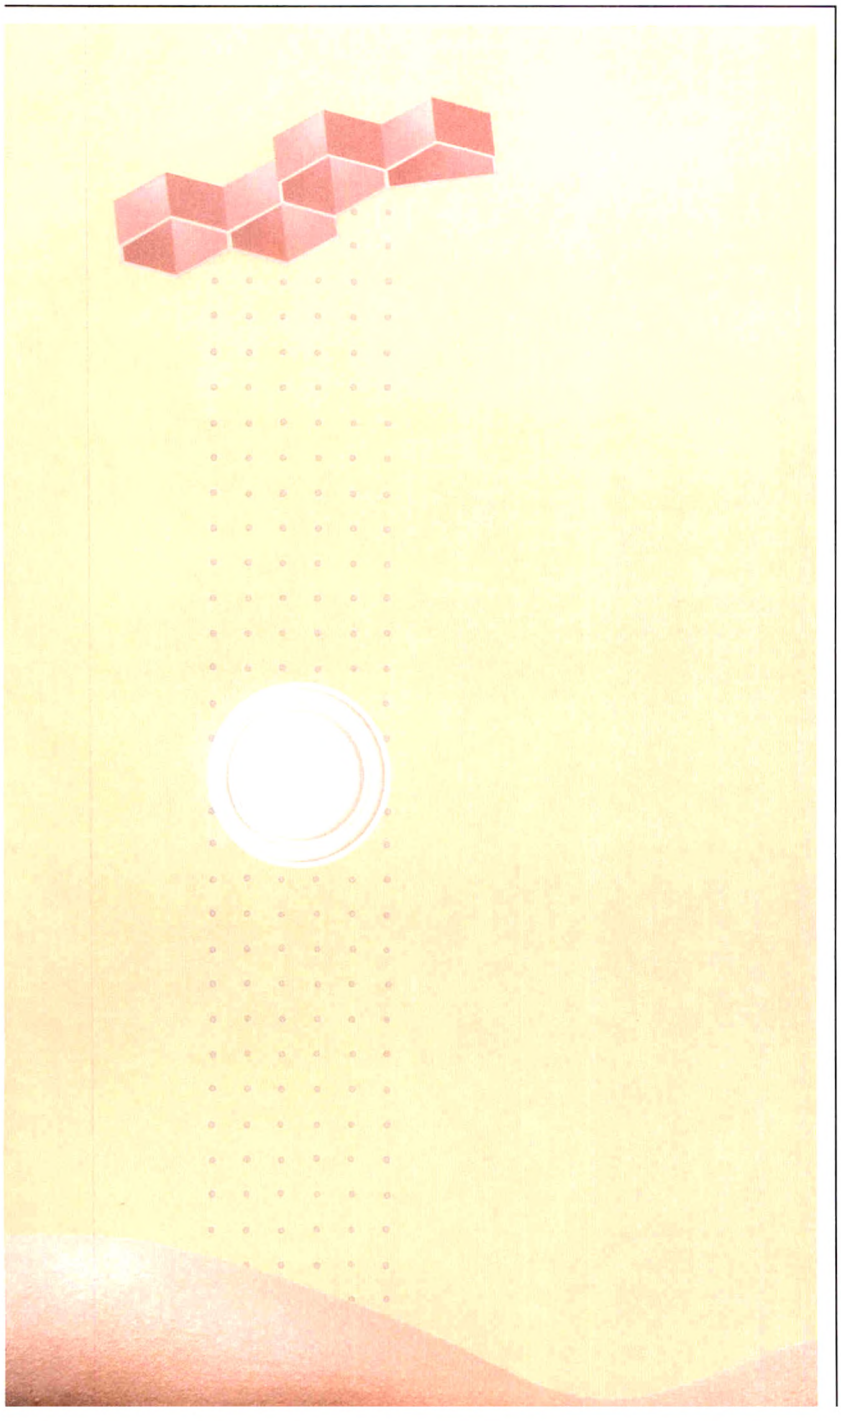
Now

The next generation of estrogen replacement therapy...



transdermal delivery

ESTRADERM®

estradiol transdermal syster

Combines the advantages of transdermal delivery...

A specially designed transdermal delivery system

Providing the natural ovarian estroge (17-beta estradiol) directly to the bloodstream and target organs; with no first-pass liver metabolism, permit use of extremely low dosage

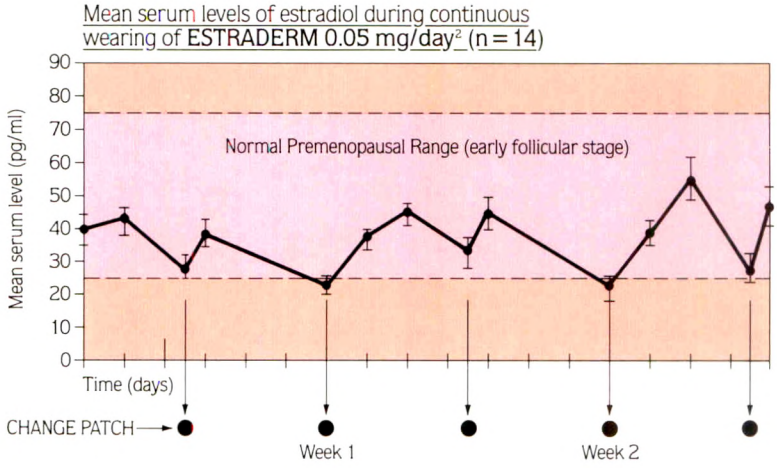
Effectively controls estrogen deficiency symptoms

Steady-state relief of hot flashes, othe menopausal symptoms associated wit hot flashes, and vaginal discomfort

Well tolerated

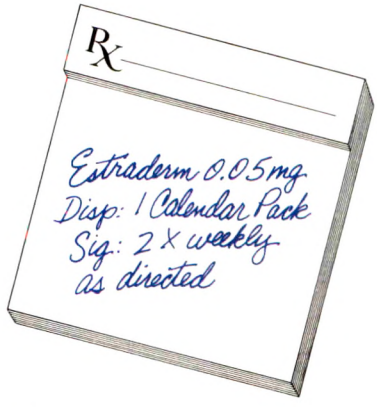
Very low incidence of systemic side effects...few local problems of consequence

Easy to use; transdermal delivery preferred 3:1 by patients over tablets[1]



Usual starting dose: a 0.05-mg syste changed twice weekly

C I B A



with the benefits of estrogen replacement

Restores and maintains premenopausal estradiol serum levels

estores estradiol levels to near-normal premenopausal ranges
.achieves a physiologic 1:1 ratio of estradiol to estrone

Available in dose-reminder calendar packs of eight patches—0.05 mg/0.1 mg

ESTRADERM®

estradiol transdermal system

Continuous delivery for twice-weekly application.
BRIEF SUMMARY OF PRESCRIBING INFORMATION.
PLEASE SEE FULL PRESCRIBING INFORMATION.

ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than 1 year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer-reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.

The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5-13.9 times greater than in nonusers. The risk appears to depend both on duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen.

Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy.

There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that women who had been exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than four per 1000 exposures. Furthermore, a high percentage of such exposed women (30-90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data on the use of other estrogens are not available, it cannot be presumed they would not induce similar changes.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case control study estimated a 4.7-fold increased risk of limb-reduction defects in infants who had been exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one per 1000.

In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses.

If Estraderm is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and of the advisability of continuation of the pregnancy.

INDICATIONS AND USAGE

Estraderm is indicated for the treatment of the following: moderate-to-severe vasomotor symptoms associated with menopause; female hypogonadism; female castration; primary ovarian failure; and atrophic conditions caused by deficient endogenous estrogen production, such as atrophic vaginitis and kraurosis vulvae.

Studies of the addition of a progestin for seven or more days of a cycle of estrogen administration have reported a lowered incidence of endometrial hyperplasia. Morphological and biochemical studies of endometrium suggest that 12 to 13 days of progestin are needed to provide maximal maturation of the endometrium and to eliminate any hyperplastic changes. Whether this will provide protection from endometrial carcinoma has not been clearly established. There are possible additional risks that may be associated with the inclusion of progestin in estrogen replacement regimens. The potential risks include adverse effects on carbohydrate and lipid metabolism. The choice of progestin and dosage may be important in minimizing these adverse effects.

CONTRAINDICATIONS

Estrogens should not be used in women or men with any of the following conditions:

1. known or suspected cancer of the breast;
2. known or suspected estrogen-dependent neoplasia;
3. known or suspected pregnancy (see Boxed Warning);
4. undiagnosed abnormal genital bleeding;
5. active thrombophlebitis or thromboembolic disorders;
6. history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use.

WARNINGS

1. Induction of Malignant Neoplasms. Long-term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. There are now reports that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning.)

At the present time, there is no satisfactory evidence that estrogens given to postmenopausal women increase the risk of breast cancer, although a recent long-term follow-up of a single physician's practice has raised this possibility. Because of the animal data, there is a need for caution in prescribing estrogens for women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms.

2. Gallbladder Disease. A recent study has reported a two- to threefold increase in the risk of surgically confirmed gallbladder disease in postmenopausal women receiving oral estrogens, similar to the twofold increase previously noted in users of oral contraceptives.

3. Effects Similar to Those Caused by Estrogen-Progestogen Oral Contraceptives. There are several serious adverse effects of oral contraceptives and other high-dose oral estrogen treatments, most of which have not, up to now, been documented as consequences of postmenopausal estrogen replacement therapy. This may reflect the comparatively low doses of estrogen used in postmenopausal women.

a. Thromboembolic Disease. It is now well established that users of oral contraceptives have an increased risk of various thromboembolic and thrombotic vascular diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. There is evidence that the risk of several of these adverse reactions is related to the dose of the drug. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least four weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization.

While an increased rate of thromboembolic and thrombotic disease in postmenopausal users of estrogens has not been found, this does not rule out the possibility that such an increase may be present or that subgroups of women who have underlying risk factors or who are receiving relatively large doses of estrogens may have increased risk. Therefore, estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders, and they should not be used in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed.

Large doses of estrogen (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown in a large prospective clinical trial in men to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis. When estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptive use should be considered a clear risk.

b. Hepatic Adenoma. Benign hepatic adenomas have been associated with the use of oral contraceptives. Although benign and rare, these tumors may rupture and cause death from intra-abdominal hemorrhage. Such lesions have not yet been reported in association with other estrogen or progestogen preparations, but they should be considered if abdominal pain and tenderness, abdominal mass, or hypovolemic shock occurs in patients receiving estrogen. Hepatocellular carcinoma has also been reported in women taking estrogen-containing oral contraceptives. The causal relationship of this malignancy to these drugs is not known.

c. Elevated Blood Pressure. Women using oral contraceptives sometimes experience increased blood pressure which, in most cases, returns to normal upon discontinuing the drug. There is now a report that this may occur with use of oral estrogens in the menopause and blood pressure should be monitored with estrogen use, especially if high doses are used. Ethinyl estradiol and conjugated estrogens have been shown to increase renin substrate. In contrast to these oral estrogens, transdermally administered estradiol does not affect renin substrate.

d. Glucose Tolerance. A worsening of glucose tolerance has been observed in a significant percentage of patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed while receiving estrogen.

4. Hypercalcemia. Administration of high doses of estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases. If hypercalcemia occurs, use of the drug should be stopped and appropriate measures should be taken to reduce the serum calcium level.

PRECAUTIONS

General

1. A complete medical and family history should be taken before initiation of any estrogen therapy. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, as well as a cervical Papanicolaou test. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed.
2. Because estrogens may cause some degree of fluid retention, careful observation is required when conditions that might be influenced by this factor are present (e.g., asthma, epilepsy, migraine, and cardiac or renal dysfunction).
3. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as uterine bleeding, mastodynia, etc.
4. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Estrogens should be used with caution in patients who have or have had endometriosis.
5. Oral contraceptives appear to be associated with an increased incidence of mental depression. Although it is not clear whether this is due to the estrogenic or progestogenic component of the contraceptive, patients with a history of depression should be carefully observed.
6. Preexisting uterine leiomyomata may increase in size during prolonged estrogen use. If this occurs, estrogen therapy should be discontinued while the cause is investigated.
7. In patients with a history of jaundice during pregnancy, there is an increased risk that jaundice will recur with the use of estrogen-containing oral contraceptives. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated.
8. Estrogens may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients.
9. Because the prolonged use of estrogens influences the metabolism of calcium and phosphorus, estrogens should be used with caution in patients with metabolic bone diseases associated with hypercalcemia and in patients with renal insufficiency.

Drug/Laboratory Test Interactions

The results of certain endocrine and liver function tests may be affected by estrogen-containing oral contraceptives. The following changes have been observed with large doses of oral estrogen:

1. increased sulfobromophthalein retention;
2. increased prothrombin time; increased factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability;
3. increased thyroxine-binding globulin (TBG), leading to increased circulating total thyroid hormone (T_4) as measured by column or radioimmunoassay; free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered; TBG was not affected in clinical trials of Estraderm;
4. reduced response to the metyrapone test;
5. reduced serum folate concentration;
6. increased serum triglyceride and phospholipid concentration, and decreased pregnanediol excretion.

The pathologist should be informed that the patient is receiving estrogen therapy when relevant specimens are submitted.

Carcinogenesis, Mutagenesis, Impairment of Fertility

See **WARNINGS** and Boxed Warning.

Long-term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

Pregnancy Category X

See **CONTRAINDICATIONS** and Boxed Warning.

Estrogens should not be used during pregnancy.

Nursing Mothers

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS

See **WARNINGS** and Boxed Warning regarding potential adverse effects on the fetus, induction of malignant neoplasms, increased incidence of gallbladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.

The most commonly reported adverse reaction to Estraderm in clinical trials was redness and irritation at the application site. This occurred in about 17% of the women treated and caused approximately 2% to discontinue therapy. Reports of rash have been rare.

The following additional adverse reactions have been reported with estrogenic therapy, including oral contraceptives:

Genitourinary System: Breakthrough bleeding, spotting, change in menstrual flow; increase in size of uterine fibromyomata; change in cervical erosion and amount of cervical secretion.

Endocrine: Breast tenderness, breast enlargement.

Gastrointestinal: Nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice have been observed with oral estrogen therapy.

Eyes: Steepening of corneal curvature; intolerance to contact lenses.

Central Nervous System: Headache, migraine, dizziness.

Miscellaneous: Change in weight, edema, change in libido.

Do not store above 86°F (30°C).

Do not store unpouched. Apply immediately upon removal from the protective pouch.

CAUTION: Federal law prohibits dispensing without prescription.

When you find yourself spending more time marketing your private practice, collecting receivables and hiring/training office personnel than you are able to spend seeing patients, perhaps it's time to explore career opportunities with GENERAL MED.

And when you find your malpractice insurance, benefits for you and your employees and office expenses cutting further into your profits, perhaps it's time to explore career opportunities with GENERAL MED.

GENERAL MED is an HMO serving the Southern California counties of Orange, Los Angeles, San Bernardino, Riverside and San Diego. We handle the entire business end of a medical practice. In addition, we offer a very competitive salary and excellent benefits—including employer paid malpractice, comprehensive health benefits, life insurance, disability insurance, vacation, CME time and a 401k plan.

It has been said that Health Maintenance Organizations are the "wave of the future". Why not "catch the wave" with GENERAL MED.

If you are Board Certified (or Eligible) in your Obstetrics/Gynecology and possess a California license, please send your CV to:

DEFINING THE DIRECTION OF OC EVOLUTION

WITH THE ADVANCED DESIGN OF

TRI-LEVLEN™

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

No other OC regimen phases *both* hormones

▼

Provides the *lowest* monthly dose of both estrogen and progestogen

▼

Little or no effect on lipid metabolism[1-5]*

▼

Low overall incidence of breakthrough bleeding[6]

*Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptom of serious disease and discontinue oral contraceptive therapy when appropriate. These data represent only the results of selected studies. Therefore, before prescribing, the physician should read and remain alert to all data found in the complete prescribing information for the product. Please also see brief summary of prescribing information on the last page of advertisement.

BERLEX Dedicated to innovation in OB/GYN medicine

TRI·LEVLEN™ 28
TRI·LEVLEN™ 21

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

BRIEF SUMMARY

Tri-Levlen™—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses. The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information and package insert.

Carbon dioxide laser laparoscopy performed with a flexible fiber in humans

Michael S. Baggish, M.D., Pavlos Baltoyannis, M.D., Shawky Badawy, M.D., and Doris Laurey, R.N.

Syracuse, New York

A flexible carbon dioxide laser fiber delivery system was used in conjunction with the laparoscope to treat 12 women. The 77 by 2 mm hollow fiber could subtend an arc of 90 degrees without significant loss of power or unfavorably affecting the delivery mode. As many as 20 W of power was transmitted through the fiber; however, carbon dioxide gas flow rates as high as 2000 cc/min reduced power by approximately 25%. Replaceable tips preserved fiber integrity to the extent that a single fiber could be reused repeatedly and gas sterilized without jeopardizing laser transmission. Of the 12 cases, endometriotic implants were vaporized in eight women, adhesiolysis was performed in four women, endometrial cysts were drained in two women, and vaporization of myomata was accomplished in two patients. The fiber was also used as a manipulating instrument and could be internally bent with a grasping forceps to better site the laser beam on a lesion. No complications related to the use of the carbon dioxide laser fiber were observed. The safety aspects of carbon dioxide laser fiber technology are not inconsiderable and could provide laser laparoscopy with an extra margin of security. (Am J Obstet Gynecol 1987;157:1129-33.)

Key words: Carbon dioxide laser fiber, laser laparoscopy with carbon dioxide fiber, flexible carbon dioxide laser fiber

The carbon dioxide laser is the most useful and widely used system for gynecologic laser surgery because of its excellent control and superior vaporizing capabilities. The major drawback in using the carbon dioxide laser through endoscopes has been the lack of a small-caliber, flexible delivery system. Until recently the search for a carbon dioxide laser fiber had been elusive.

The first report of a practical and functional carbon dioxide fiber was published by Baggish and Elbakry[1] in 1986. This flexible fiber was used successfully to perform operative laparoscopy on rabbits and deliver the carbon dioxide laser beam with an acceptable mode and power retention. Although laser laparoscopy has proved to be an increasingly accepted, least invasive technique for the treatment of many pathologic conditions within the abdominal cavity, its major deficiency focuses on a cumbersome delivery system.[2-4] The single-puncture operating laparoscope delivers the laser beam through a 5 to 6 mm diameter operating channel and provides a relatively easy way to perform operative laser endoscopy. The problems associated with this technique relate to the focus of the laser beam being asynchronous to that of the laparoscope and the fact that the operator cannot accurately determine what structure(s) may be interposed between the laser beam and the target. Recent reports of injuries that involved intestinal trauma during laser laparoscopy with single-puncture methodology reinforce this concern. Use of a hollow laser probe through a second or third puncture allows the operator to manipulate the laser beam independent of the endoscope and to always know what lies between the laser probe and the target. Unfortunately, these rigid metal tubes measure 7 to 8 mm in diameter and require large trocars.

Material and method

The carbon dioxide laser flexible fiber was provided and manufactured by Xanar, Inc., Colorado Springs, Colorado. The current system is in reality a hollow fiber guide measuring 77 cm in length with a total outer diameter measuring 2.0 mm and an inner cross section of 0.5 mm per side (Fig. 1). The fiber is constructed of beryllium copper with a cladding of kymar. Interchangeable (disposable) tips measuring 1 mm outer diameter by 20 mm long are inserted into the operative end of the fiber and serve to protect the interior from particulate matter deposits (Fig. 2). All fibers can be sterilized in plastic tubes by standard gas sterilization techniques that use ethylene oxide. The fiber is flexible to the extent that it can subtend an arc of 90 degrees without loss of function. The fiber is attached to the

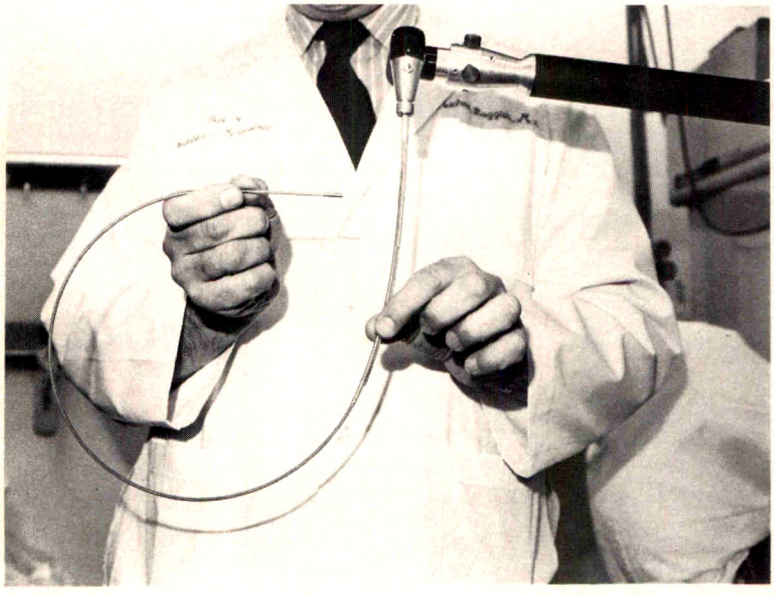

Fig. 2. The fiber is very flexible and can subtend an arc of 90 degrees. Here it is shown attached to the laser head by an intervening special arm fitted with an articulating knuckle.

laser head of a Xanar XA-20 carbon dioxide laser (maximum output 20 W) via the interposition of a special arm measuring 58 cm. The terminus of the arm is fitted with a mobile knuckle and a gas inlet. The arm also incorporates a focusing lens and a simple alignment mechanism. The latter can easily be adjusted before initiation of the operative procedure without having to actually attach the fiber to the arm. As a result of previous laboratory investigations, blower carbon dioxide flow is adjusted to deliver gas through the fiber at a flow rate of 1900 cc/min (Fig. 3).

A small trocar (Carl Storz, Culver City, Calif.) measuring 14 cm long by 3.5 mm outer diameter is used to facilitate entry of the fiber into the abdominal cavity.

Operative procedure

Table I lists the patients treated, together with their respective diagnoses. A total of 12 women underwent carbon dioxide laser laparoscopy with the flexible fiber from March 1986 to February 1987. Each patient had previously read and signed a detailed informed consent. All operations were performed under general endotracheal anesthesia. Before surgery the vagina and abdomen were prepared with povidone-iodine (Betadine). The urinary bladder was catheterized and emptied of urine. A single-toothed tenaculum was attached to the cervix, and a Cohen-Eder cannula (Eder Instrument Co., Chicago, Ill.) was placed in the cervix for manipulation. The abdomen was draped and the operative field was blocked with moist cotton towels. The fiber was attached to the laser arm, and the alignment was quickly rechecked by firing several spots into a wooden tongue depresser. A standard laparoscopy was performed with a touhy (epidural) needle to create a carbon dioxide pneumoperitoneum. Three liters of carbon dioxide gas were pumped into the belly by an insufflator delivering 2.5 L/minflow. A 7 mm outer diameter trocar was inserted through a 1 cm infraum-

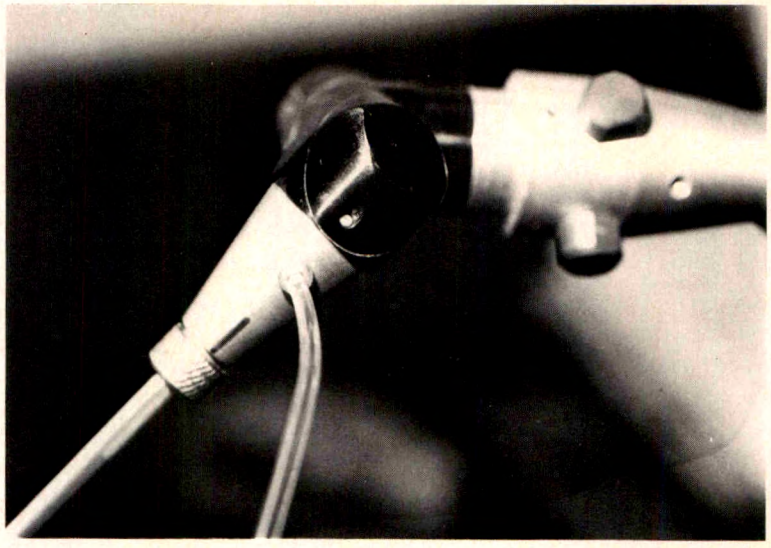

Fig. 3. A carbon dioxide blower tube is attached to an inlet on the knuckle pictured in Fig. 2. Carbon dioxide flow is adjusted to a rate of approximately 1900 cc/min. The constant flow of carbon dioxide gas keeps debris and vapor from obstructing the fiber lumen.

*Stage II.
†Stage III (American Fertility Society Classification).

bilical incision followed by a 6.5 mm outer diameter laparoscope (Carl Storz). A second puncture was placed just below the pubic hair line to the left of midline by means of a 7 mm trocar. A combination smoke evacuator irrigation cannula (Eder Instrument Co.) was inserted through this entry port. Inspection of the pelvic viscera was then carried out. Next, a 3.5 mm trocar was inserted approximately 3 to 4 cm below the umbilicus to the right of the midline through which the laser fiber was passed. The carbon dioxide flow through the fiber was activated and was sufficient to maintain abdominal distension throughout the procedure. Alternatively, a standard 9 mm single puncture laparoscope with a 3.5 mm operating channel (Richard Wolf) was used in four cases. The laser fiber was conveniently inserted through the operating channel. When the operator fired the laser, smoke was also discharged from the field. The power was turned up to 10 to 20 W (Table I).

The fiber was brought to within 2 to 3 mm of the lesion to be treated, and the laser was then fired, usually at a continuous time setting. For strategically located lesions, the laser was time gated at 0.2 second for more accurate control. The second puncture irrigating-evacuation cannula could also double as a backstop for the laser beam. The actual fiber was stiff enough to perform fine manipulations of structures with the ab-

domen. The highest power settings were used to cut adhesions and vaporize myomas.

Endometriomas were opened at 20 W and the contents were drained. The fiber could be inserted directly into the cyst and the lining was vaporized by reducing the power to 10 W. Endometrial implants were vaporized at 10 W at time-gated 0.1 to 0.2 bursts or at continuous time exposure. Seedling myomas could be vaporized outright at 20 W or the serosa incised at 10 to 15 W followed by capsular vaporization at 15 W. The myoma was then teased out with the fiber and grasping forceps. Adhesions were eliminated with the evacuator-irrigation probe as a backstop and cutting the adhesions at 20 W. As in the rabbit studies, maximal impact power was observed at a distance of 2 to 3 mm.

When the procedure was finished the char material was washed away from the ablated areas with heparinized lactated Ringer's solution (5000 U of heparin/L of sterile lactated Ringer's solution). Excess irrigation fluid was sucked out of the cul de sac. The pneumoperitoneum was allowed to escape from the abdominal cavity and all instruments were withdrawn. The wounds were closed with interrupted 3-0 vicryl sutures.

When lesions located on the right portion of the pelvis could not be conveniently treated by the initial introductory site of the fiber, a third or even fourth stab could be placed in the midline or to the left of the midline to allow better positioning. The fiber could be manipulated within the abdomen to better impact a lesion by using a grasping forceps to induce a small bend. This unique maneuver is a tremendous advantage for performing very precise laparoscopic surgery. Virtually any lesion that can be seen can also be vaporized or incised. When bleeding occurs, the fiber can be withdrawn to a distance of 4 to 5 mm and coagulation brought about. In addition, the carbon dioxide flow through the fiber helped blow away blood while the bleeding point was coagulated.

Results

Ablative lesions produced by the carbon dioxide laser fiber were identical to those produced by the laser free-hand piece. At a target distance of 2 mm, a spot measuring 0.8 mm was created. The histologic findings of these lesions were previously described.[1] A reduction of laser power was observed when gas flow through the fiber was increased. Flow rates above 2000 cc/mm produced an estimated 40% reduction of power. At flow rates of 2000 cc, power was estimated to be reduced by 25%. When no gas was instilled through the fiber, laser smoke and moisture were deposited within the lumen of the guide. This led to markedly reduced laser power and eventually to a functionless fiber. Interior heat resulting from the laser impacting on the debris also caused damage to the interior-coating material. Certain fiber configurations also led to a reduction of laser power. The worst configuration was reverse S shaped and reduced power by approximatley 50%. Laboratory evaluation that used a power meter confirmed the extent of power reduction. The fiber regained power on straightening, that is, the reduction was in no way permanent. One fiber could be used repeatedly without loss of power or mode. During the study, fibers were alternated, that is, one was gas sterilized while the other was in use except on occasions when more than one laser case was posted during the same day. The removable fiber tips were replaced liberally; sometimes two were used during a single case.

During the laparoscopic procedure, the carbon dioxide flow through the fiber was more than adequate to maintain the pneumoperitoneum. In fact no gas was ever delivered during laser surgery through the laparoscopic insufflator. Because of this constant flow of gas, the assistant maintained a vigil for overdistension of the abdominal wall and allowed gas to escape on a timely basis.

Of 12 cases treated, two pregnancies have been reported. One patient treated early in the series was delivered. One woman is currently pregnant. Four patients were treated for pelvic pain and have reported an improvement in their symptoms. One of these women underwent drainage of an endometrioma and was recently seen. Although this woman reported general relief of pain, she nevertheless complained of deep pressure within the pelvis and is currently being evaluated for a recurrence of her endometrial cyst. The two women who had vaporization and/or excision of myomata had surgery too recently to obtain suitable follow-up information.

All patients were examined 4 to 6 weeks after surgery. All wounds healed nicely. The patients were uniformly pleased because of the good cosmetic results from the small scars that resulted from the 3 mm stab wounds made for the entry of the small trocar through which the fiber gained access into the abdominal cavity. No complications related to the use of the carbon dioxide laser fiber were observed or reported during this study.

Comment

This study demonstrated several advantages of a carbon dioxide laser fiber system when compared with conventional, rigid, metal tube delivery. The principal benefits were the relatively small-fiber diameter and flexibility of the fiber. The ability to use the fiber in conjunction with single-puncture laparoscopy while enjoying the advantages of visualizing the fiber and the target at all times added significant safety factors to this methodology.

The construction of the fibers used in this study, that is, beryllium copper, offered greater flexibility and du-

rability compared with the dielectrically coated aluminum fiber used in our previous study. In that earlier study, once fiber alignment was completed, further realignment was unnecessary. No helium neon beam was present and it was not needed. The major disadvantage of this system centered on the overall short length of the fibers. Longer fibers would be advantageous, since the laser arm could be placed in a more remote location from the operative field. The crater diameter, depth, and peripheral coagulation effect were at all times predicated on the fiber-to-target distance and the laser power setting. The stiffer fiber construction had certain advantages when compared with smaller diameter, highly flexible quartz fibers.[5,6] The ability to manipulate structures between lasering cycles provided better exposure and proved to be a highly advantageous operative maneuver.

The safety aspects of carbon dioxide laser fiber technology are not inconsiderable and provide laser laparoscopy with an extra margin of security for both the patient and the surgeon. Based on the data obtained in this study and previous work, the carbon dioxide laser fiber should offer a favorable alternative for laser and operative endoscopy. The technique is easier to learn than those currently available for laser laparoscopy.

Decreased elastic fibers and desmosine content in incompetent cervix

Phyllis C. Leppert, M.D., Ph.D., Shiu Yeh Yu, Ph.D., Stephen Keller, Ph.D., Joseph Cerreta, Ph.D., and Ines Mandl, Ph.D.

Incompetence of the uterine cervix is a syndrome of painless, progressive dilatation and effacement occurring between the sixteenth and twenty-fourth weeks of gestation that represents abnormal functioning. It may serve as a model to elucidate normal function. Because the incompetent cervix results in painless opening of this organ without uterine contraction before term gestation, it is considered one of the causes of midtrimester spontaneous abortion, habitual spontaneous abortion, and early preterm labor. Untreated, it leads to rapid expulsion and often death of the fetus. We used light microscopy to compare decreased elastic fibers in incompetent cervices with those of normal nonpregnant and pregnant cervices. Morphologic analysis of this difference was extended to biochemical quantification of elastin content in one patient with cervical incompetence. The decrease in elastin suggests that one function of cervical elastin may be to maintain a closed and undilated cervix throughout gestation. There may be a relationship between changes in cross-linked elastin and the incompetent cervix; further studies are therefore indicated. (Am J Obstet Gynecol 1987;157:1134-9.)

Key words: Incompetent cervix, elastin, elastase, gestation, parturition

Incompetence of the uterine cervix is a syndrome defined as painless, progressive dilatation and effacement that occurs between the sixteenth and twenty-fourth week of gestation.[1, 2] It is considered one of the causes of habitual spontaneous abortion, midtrimester abortion, and early preterm labor. Untreated, it leads to sudden rupture of the amnion and chorion, followed by rapid expulsion of the fetus.[3, 4] Because this syndrome represents an abnormal function of the cervix, it may serve as a model to elucidate normal function.

We have previously reported that elastin is present in the uterine cervix and can be assayed by measurement of the elastin-specific cross-links desmosine and isodesmosine.[5, 6] We have also established that the elastic fibers are organized in a band 20 to 30 μm thick, parallel to and between the collagen fibers from the periphery to the external os and toward the internal os.[7] These fibers are organized in such a way that after effacement or thinning of the cervix before active labor, they would be just beneath the fetal presenting part. It is of considerable interest to determine the amount of elastin in the clinically incompetent cervix, as any deviation from normal could suggest a role for elastin in gestation and parturition.

Methods

Diagnosis of incompetent cervix. For the purposes of our study, the criteria for inclusion in the diagnostic category of incompetent cervix were documented evidence of progressive, painless dilatation without uterine contraction, and effacement of the cervix in the late first or second trimester, a history of previous painless dilatation of the cervix and/or a history of cervical trauma, such as a difficult dilatation and curettage, and a cerclage in place before the time of delivery.

Human tissue sources. All subjects were recruited into the study after individual informed consent was given and the approval of the institutional review board for research involving humans was granted. In the study period described, two patients with incompetent cervix declined to participate.

Six patients who met the criteria for incompetent cervix underwent anterior, full-thickness 2 by 2.5 cm wedge biopsy from the external os toward the anatomic internal os immediately after delivery. These were samples 1 to 6.

Six uterine cervical tissue specimens were obtained from women either at the time of hysterectomy or as a full-thickness 4 by 5 cm anterior wedge biopsy from the external os to the internal os immediately after

delivery. These were samples 7 to 12. Sample 7 consisted of the whole cervix of a woman at 40 weeks of normal gestation who underwent a cesarean hysterectomy. The cervix was identified and dissected free from the lower uterine segment. Sample 8 consisted of anterior and posterior wedges from the hysterectomy specimen of a woman who had a ruptured cornual pregnancy at 16 weeks' gestation. Sample 9 consisted of anterior and posterior wedges from the cervix of a woman 30 weeks pregnant who had a cesarean hysterectomy. Tissue sample 10 was the whole cervix of a nonpregnant woman who had a hysterectomy for benign disease. Sample 11 was obtained from a woman who had a cerclage at 12 weeks' gestation and was delivered at 38 weeks; before placement of the cerclage she had had uterine contractions noted by both palpation and electronic fetal monitoring and thus did not have classical incompetent cervix. Sample 12 was an anterior wedge of cervix obtained immediately after delivery from a woman with a classic history of incompetent uterine cervix, including painless, cervical dilatation in four previous pregnancies. She had a cervical cerclage at 12 weeks.

Seven additional samples (13 to 19) were all obtained from nonpregnant patients at the time of hysterectomy for benign disease.

Light microscopic studies. Cervical biopsy tissue specimens 1 to 6 obtained from patients who met criteria for incompetent cervix and from samples 7, 8, 9, and 13 to 19 were immediately fixed in phosphate-buffered formalin. These tissues (6 mm thick) were processed routinely for light microscopy. They were stained by the modified iron-hematoxylin stain for elastin described by Musto,[8] which reveals sharply outlined elastin fibers. Briefly, tissues were deparaffined and hydrated. They were mordanted in a saturated solution of alcoholic Bouin's fluid at 55° to 60° C for 10 minutes. The sections were then washed in tap water, rinsed briefly in distilled water, and stained with the elastin stain for 45 minutes. After staining, the sections were washed in tap water, rinsed in distilled water, and stained with woodstain scarlet for 5 minutes. After a second water wash the sections were treated with 2% phosphotungstic acid (2 minutes) and with 5% acetic acid (5 minutes), rinsed in distilled water, dehydrated in alcohol, then stained in 1% alcoholic saffron (5 minutes). Sections were then dehydrated and cleared before mounting. With this stain the elastic fibers stain black and are sharply outlined, nuclei stain dark purple to black, muscle cells stain pale red, and collagen stains yellow. Multiple serial sections were prepared at various tissue levels of the cervix. All sections were thoroughly searched under the high-power occular setting for elastic fibers. Results were compared as number of fibers seen in at least 10 high-power fields.

Biochemical analysis

Extraction of crude connective tissue. Tissues from the six cervical specimens 7 to 12 derived from five normal cervices and one incompetent cervix were frozen immediately at −20° C and then stored until processing. After thawing, the tissue was trimmed, weighed, and minced thoroughly with scissors. The tissue was then homogenized in a blender with 1 mol/L sodium chloride, washed and resuspended in 1 mol/L sodium chloride, and stirred overnight at 5° C. This step was repeated a total of five times. After the fifth centrifugation, the residue was washed three times in deionized water and lyophilized. The dry powder was then extracted three times in cold *n*-butanol and three times in cold acetone to remove lipids and was then dried overnight. This material was designated crude connective tissue.

Preparation of samples for biochemical assays. Ten milligrams of each sample (with the exception of sample 6, in which 2.5 mg was used) was hydrolyzed in 1 ml of 6N hydrochloric acid for 48 hours at 116° C. The hydrolysate was filtered, diluted with 20 ml of water, and lyophilized. The residue was dissolved in 10 ml of water and lyophilized to remove excess hydrochloric acid, after which the process was repeated. The hy-

Fig. 2. Photomicrograph of sample 3 from a subject who met the criteria for incompetent cervix. Note that the elastic fibers are decreased in number compared with those of a normal cervix and they appear to be broken *(arrow)*. *E*, Epithelium. (Original magnification ×310.)

drochloric acid–free residue was dissolved in 3 ml of water.

Radioimmunoassay for desmosine. A 0.1 mg aliquot of the hydrolysate was used for the desmosine assay. This aliquot was diluted with isotonic veronal-buffered saline solution at pH 7.2 and was assayed for demosine by a monospecific radioimmunoassay as previously described.[9] Briefly, aliquots of hydrolysate were mixed with rabbit anti–desmosine serum and incubated at room temperature for 15 minutes. Radioactive desmosine labeled with Bolton-Hunter-^{125}I reagent (New England Nuclear, Boston, Massachusetts) was added and further incubated for 1 hour at 30° C. The antibody and desmosine complex was separated by centrifugation in the presence of polyethylene glycol according to the method of Desbuquois and Aurbach.[10] One hundred microliters of bovine γ-globulin (1.75 mg/ml in 0.85% sodium chloride) was added as a carrier, followed by 0.5 ml of cold 25% polyethylene glycol solution (in 0.1 mol/L sodium borate, pH 8.0). The precipitate was separated by centrifugation at 4000 rpm at 4° C for 30 minutes and then washed once with 0.5 ml of cold 12.5% polyethylene glycol solution. Radioactivity of the precipitate was measured in a gamma counter. Standard desmosine solutions were used from 0.5 to 16 pmol in 100 μl of isotonic veronal-buffered saline solution. Each assay was repeated on each sample from five to 16 times.

Isolation of elastin. Approximately 200 mg of samples 7 and 9 (crude connective tissue) was extracted with 5 ml of 0.1 mol/L sodium hydroxide at 98° C for 45 minutes according to the method of Lansing et al.[11] The residue was then hydrolyzed with 6N hydrochloric acid and analyzed for desmosine by the radioimmunoassay.

Calculation of elastin percent in tissue. The amount of elastin was calculated by converting desmosine at a value of 13.9 nmol desmosine per milligram elastin. Results are expressed as desmosine or elastin per milligram of dry, defatted insoluble residue. Percent elastin is expressed as percent per crude connective tissue on the basis of desmosine content.

Results

In five of the six anterior wedge biopsy samples derived from the cervices of women with the clinical criteria of incompetent cervix, light microscopy revealed no elastic fibers (Table I, Figs. 1 and 2). The gestational ages of the pregnancies ranged from 8 to 40 weeks. A sample obtained at 25 weeks' gestation revealed elastic fibers; however, these fibers were decreased in number and were broken.

All 10 of the samples from normal cervices clearly showed elastic fibers that appeared to be oriented in a bandlike configuration, as recently demonstrated in this laboratory.[7] The presence of elastic fibers was not affected by the age of the woman or her parity.

Fig. 1 is a photomicrograph of an incompetent cervix showing the absence of elastic fibers, and Fig. 3 is a normal cervix photomicrograph with clear evidence of elastic fibers. Fig. 2 is a photomicrograph of the cervical tissue of a patient who had clinical evidence of incompetent cervix. It reveals broken elastic fibers that appear decreased in amount.

Results of the biochemical studies demonstrate that the desmosine content of the cervical tissue ranges from 102 ± 4 (SEM) to 287 ± 12 (SEM) pmol/mg, the lowest amount being present in the tissue from a woman with incompetent cervix as compared with normal cervical tissue. This represents a considerable decrease in mature cross-linked elastin in the incompetent cervix (Table II, Fig. 4). The nonpregnant patient had the highest amount of elastin, as calculated by both percent elastin in the crude connective tissue fraction and by picomoles desmosine per milligram tissue, almost double the amount found in cervices from pregnant patients. Each sample was assayed repeatedly, as noted in Table II.

The results obtained on samples 7 and 9 by extraction of the crude connective tissue by the Lansing et al.[11]

procedure followed by the desmosine radioimmunoassay were similar to those obtained with the direct hydrolysate of crude connective tissue, indicating that there was no difference in the amount of this specific cross-link in the crude connective tissue and in the pure elastin extracted. These results confirm that the radioimmunossay was specific for desmosine and did not cross react with any collagen cross-links.

Comment

We used the incompetent cervix as a model to determine the role of elastin in the cervix during gestation. The diagnosis of incompetent cervix is suspected by a history of repeated painless second-trimester pregnancy loss and is confirmed by the clinical finding of a patent cervical os in pregnancy.[12-15] It is quite rare and it is suggested that the true incidence lies between 1 in 1000 and 1 in 2000 live births.[16] Past histories of women with incompetent cervix include cervical operation, especially amputation; forcible dilatation of the cervix for diagnostic curettage or termination of pregnancy; trauma to the cervix during childbirth; and exposure in utero to diethylstilbestrol.[15] In approximately 2% of women who have been diagnosed as having an incompetent cervix, there is no apparent cause.[15] Theoretically, it could be postulated that trauma to the cervix destroyed the elastic fibers, which run in a band just under the epithelium of the endocervical canal.[7] This would explain why the incompetent cervix traditionally included a history of cervical trauma.[15] Our tissue sample 12 was obtained from a woman with a history of

three midtrimester pregnancy losses after a spontaneous abortion at 12 weeks. All of these losses followed painless dilatation of the cervix. Because all wedge biopsy specimens were obtained from the anterior and in some cases from both the anterior and posterior cervix in the area of the endocervical canal, where the

elastic fibers are normally located, the decrease in elastin content cannot be considered to be due to sampling errors. Whether the decreased elastin content is due to loss of elastin because of trauma or to an unknown cause in these cases cannot be determined at this time. Nevertheless, it is obvious that the clinical course in this study of the pregnancies complicated by incompetent cervix was very different from that of normal gestation in which cervical elastin was not decreased.

Elastin has been shown thermodynamically to effectively store elastic energy and release it as well as to stretch and retract, and is considered to have high rebound resilience or reversible extensibility.[17, 18] This property would be important in maintaining a closed cervix during gestation.

Unfortunately, it was not possible to obtain tissue from a second woman with incompetent cervix ample enough for biochemical analysis in part because of the rarity of the snydrome and the reluctance of pregnant subjects to undergo cervical biopsies.

A fairly rare clinical syndrome, the incompetent cervix was used as a "natural" experimental model to help elucidate the role of elastin in the retention of the fetus in utero. The subjects were compared with women at various weeks of gestation who had normal cervical functioning. Correlation of abnormal function of the cervix with the histologic findings of absent or decreased elastic fibers as opposed to a bandlike configuration of these fibers[7] and biochemical demonstration of decreased desmosine content in the incompetent cervix suggests that the decrease in elastin is real. It further suggests that the decrease in desmosine is not caused merely by decreased rates of cross-link formation. These differences were noted throughout all gestational ages. It is important to note that all cervical tissue studied by the radioimmunoassay was from multiparous women. Labor status did not seem to affect differences within the cervical tissue of the pregnant subjects, since specimens 7, 11, and 12 were obtained from women after the onset of physiologic labor, while spec-

imens 8 and 9 were obtained before labor. Sample 10, which had the highest amount of elastin, was obtained from a nonpregnant multiparous woman. Because leukocyte elastase is present in the cervix during gestation, presumably elastin is degraded in cervical tissue during pregnancy; this could account for the difference. Samples 7, 8, and 9 were obtained from cesarean hysterectomy specimens and the whole cervix was thus available for analysis. These samples could be studied by both biochemical and histologic methods. The other samples, which were from wedge biopsies, provided only sufficient tissue for either biochemical or histologic studies, not both.

Because women with the clinical entity of incompetent cervix have a clear, recognizable abnormality in the physiologic function of cervical tissue in pregnancy, the fact that the incompetent cervices we studied have absent or decreased elastic fibers compared with tissue from women with normal gestation indicates that elastin may contribute to the retention of the fetus throughout gestation until the onset of labor. This conclusion is further supported by the biochemical quantitation of decreased desmosine in a patient with cervical incompetence.

The technical assistance of Mark Clarke is gratefully acknowledged.

Formulas for fetal weight estimation by ultrasound measurements based on neonatal specific gravities and volumes

Norio Shinozuka, M.D., Takashi Okai, M.D., Shiro Kohzuma, M.D., Masaaki Mukubo, M.D., Chen-Ting Shih, M.D., Tsugio Maeda, M.D., Yoshinori Kuwabara, M.D., and Masahiko Mizuno, M.D.

Hongo, Bunkyo-ku, Tokyo, Japan

To improve the accuracy of fetal weight estimation by ultrasound measurement, especially in low birth weight infants, including those with intrauterine growth retardation, two new formulas were developed from a new point of view. The formulas were established by (1) actual measurements of the volumes of the neonatal head and trunk with limbs, (2) analysis of the relationship between the sizes of the parts of the fetal body measured by ultrasound examination before birth and the volumes of the parts of the neonatal body, and (3) calculation of the specific gravities of the parts of the neonatal body. The prospective study showed a high correlation between estimated weights and actual birth weights with a small range of error in infants weighing between 450 and 4800 gm. (AM J OBSTET GYNECOL 1987;157:1140-5.)

Key words: Fetal weight estimation, ultrasound, specific gravity, intrauterine growth retardation

Although many formulas for fetal weight estimation have been reported,[1-5] their accuracies are not sufficient in cases of low birth weight infants, especially those with intrauterine growth retardation (IUGR).[1-5] The reasons for incorrect estimations are as follows: (1) Most formulas were made by the regression method that uses birth weights and values for each fetal part such as biparietal diameter (BPD) and trunk diameter, obtained through ultrasonic measurements before birth. Accordingly, these formulas use the heavier coefficients for BPD, which can be measured with a smaller range of error than can trunk diameter. (2) The accuracy of any formula made by the regression method depends on the number of cases taken into consideration in devising formulas. Such formulas are not suitable for fetuses with IUGR, whose proportions are different from those of normal fetuses, because the samples used include few cases of IUGR.

For these reasons, we tried to establish more logical formulas that considered the specific gravities and the volumes of neonates.

Method

Ultrasonic measurements. Ultrasonic measurements of the fetuses included BPD, APTD (anteropostero trunk diameter), TTD (transverse trunk diameter), SL (spine length), and FL (femur length).

Each measurement was performed according to the following profile. BPD was measured from the outer edge of the anterior skull to the inner edge of the posterior skull on a section in which the cavity of septum pellucidum, the cisterna corpora quadrigemina, and the midline echo were clearly visualized.[6] APTD and TTD measurements were performed at right angles just vertical to the descending aorta where the umbilical vein was clearly visualized at a point one third to one fourth its length from the anterior abdominal wall.[6, 7]

FL was determined by measuring the length of the ossified part of the femur bone.[6]

SL was determined by measuring the spine from L-3 to T-6. L-3 was identified by visualization of the promontorium.[8]

Principle of the new formula for fetal weight estimation. The principle on which the new formula is based is illustrated in Fig. 1. The fetal body is divided into two components, the head and the trunk with limbs. The weight of the head is calculated by multiplication of the specific gravity and the volume of the head. The weight of the trunk with limbs is calculated in the same way. The volumes of each component are calculated by multiplication of the coefficients (A and B) and the parameters (BPD^3 APTD × TTD × SL)

$$\text{Fetal weight} = \underbrace{\text{Specific gravity of the head} \times A \times \underbrace{BPD^3}_{\text{Volume of the head}}}_{\text{Weight of the head}} + \underbrace{\text{Specific gravity of the trunk} \times B \times \underbrace{APTD \times TTD \times SL}_{\text{Volume of the trunk}}}_{\text{Weight of the trunk}}$$

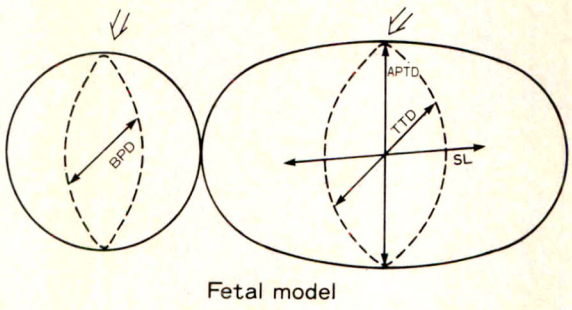

Fig. 1. Principle of the formula for fetal weight estimation. BPD^3 and APTD × TTD × SL were used as three-dimensional parameters of the head and the trunk, respectively. Coefficients A and B are the ratios of the volumes and the parameters of each part. The trunk includes the four limbs.

Table I. Number of cases entered in the prospective study and birth weight

Birth weight (gm)	*AFD*	*LFD*	*HFD*	*Total*
0-999	5	12	0	17
1000-1499	13	21	0	34
1500-1999	29	47	0	76
2000-2499	54	87	0	141
2500-2999	141	13	0	154
3000-3499	143	0	0	143
3500-	65	0	27	92
Total	450	180	27	657

AFD = Appropriate for date; LFD = light for date; HFD = heavy for date.

(Fig. 1). The coefficients are equal to the ratios of volumes and parameters. Accordingly, the weight of each component is calculated by multiplication of the specific gravity, the coefficient, and parameter.

Determination of specific gravities, coefficients (ratio of volume/parameter), and establishment of formula. The specific gravities of each part and the relationship between the volumes and the parameters were determined by the following procedures.

A. Each part of the fetuses was measured by ultrasound examination within 2 days before birth.

B. Birth weights were measured immediately after delivery.

C. The actual volumes of the heads and the trunks with limbs of the neonates were measured within 2 days after delivery. Thirty normal neonates with neither maternal complications nor any abnormalities of delivery were used. The mean gestational age was 39.1 ± 1.1 weeks (range 37 weeks, 2 days to 41 weeks, 2 days) and the mean birth weight was 3157 ± 306 gm (range 2524 to 3758 gm). The head was covered by special aluminum paper to make a mold of the head. The mold was then filled with small vesicles of forming polystyrol. The head volume was determined by measuring the volume of the vesicles with a graduated cylinder. The volume of the trunk with limbs was determined by measuring the volume of water that overflowed when the neonate was bathed. The accuracy of this method was confirmed by measuring several phantoms.

D. Using the values obtained from (A) and (B), the following ratios were calculated: A, volume of the head/BPD^3 and B, volume of the trunk with limbs/APTD × TTD × SL.

E. The specific gravities of each part were calculated by the multiple regression method using the results of (B) and (C).

F. A new formula was created that used each value obtained by these procedures. The volume of the trunk should normally be calculated with the three-dimensional parts of the trunk (APTD × TTD × SL, Fig. 1), but because it is sometimes difficult to measure SL, we also devised another formula in which FL is used instead of SL.

Prospective study. To confirm the accuracies of the

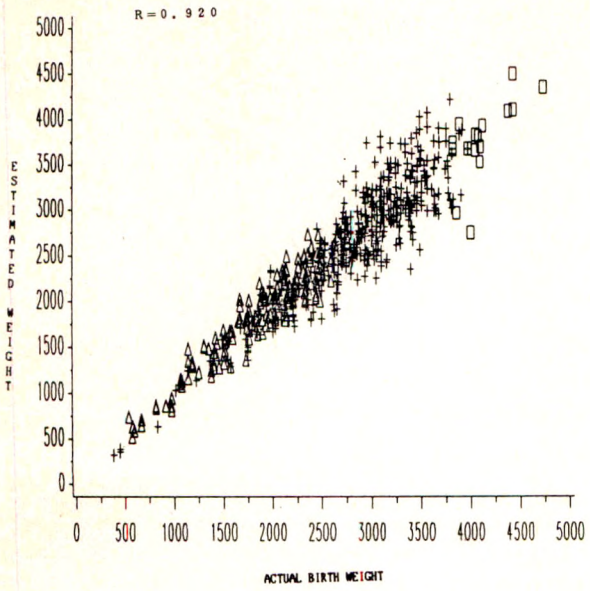

Fig. 2. Correlation between estimated weights and actual birth weights in formula 1: (△ :LFD, + :AFD, □ :HFD). (*LFD* = Light for date; *AFD* = appropriate for date; *HFD* = heavy for date.)

new formulas, a prospective study was done. The total number of cases studied was 657, including 180 cases of light for date. The gestational ages varied from 21 to 41 weeks, and the birth weights ranged from 450 to 4800 gm (Table I). All patients were ultrasonically examined within 7 days before delivery. With due regard to practical use of the formulas, the prospective study data were collected from examinations performed by several residents and specialists.

The correlations between estimated weights and actual birth weights and the errors related to birth weights were analyzed. The errors of estimation were expressed as percentages of actual birth weights: error of estimation (%) = (estimated weight − actual birth weight)/actual birth weight × 100.

All these statistical analysis were performed with a FACOM M-360 system at Tokyo University Hospital's computer center with SAS package software (version 5).

Results

Specific gravities and volume/parameter ratios. In the 30 cases studied, the specific gravities of the whole body, head, and trunk with limbs of the neonate were 1.132 ± 0.087 (mean ± SD), 1.085 and 1.132, respectively. The ratio of head volume to BPD^3, trunk with limbs volume to APTD × TTD × SL and trunk with limbs volume to APTD × TTD × FL were 0.990 ± 0.175 (mean ± SD), 2.573 ± 0.327, and 3.023 ± 0.401, respectively (Table II).

Table II. Specific gravity of neonate and relationship between volume and parameter of each part (mean ± SD)

SG of the whole body of neonate	= 1.130 ± 0.087
SG of the head	= 1.085*
SG of the trunk with limbs	= 1.132*
VH/BPD^3	= 0.990 ± 0.175
VT/APTD × TTD × SL	= 2.573 ± 0.327
VT/APTD × TTD × FL	= 3.023 ± 0.401
	(N = 30)

SG = Specific gravity; VH = volume of the head; VT = volume of the trunk with limbs.

*Specific gravity of the head and trunk with limbs were calculated values.

Table III. New formulas

(1) $1.07 \times BPD^3 + 2.91 \times APTD \times TTD \times SL$
(2) $1.07 \times BPD^3 + 3.42 \times APTD \times TTD \times FL$

New formulas. New formulas were based on the fetal model (Fig. 1). The values of specific gravities and coefficients (ratios of volumes/parameters) obtained from actual measurements were substituted. The first member of each equation means the weight of the head and the second that of the trunk with limbs (Table III).

Results of prospective study. The correlation between estimated weights and actual birth weights is shown in Fig. 2. The correlation coefficients of estimated weights and actual birth weights were 0.920 and 0.945 in formulas 1 and 2, respectively. The errors of estimation are shown in Fig. 3. The ranges of error for both formulas are shown in Tables IV and V. It was obvious that the errors were constant over a broad range of body weights from 450 to 4800 gm, and no differences of error were found among light for date, heavy for date, and appropriate for date. The error was <10% in about 70% of the cases. The error range was <15% in nearly 90% of the cases in all birth weight groups. The mean error ± SD was −0.4 ± 9.6% and −0.2 ± 9.5% in the light for date cases according to formulas 1 and 2, respectively.

Comment

Most previously reported formulas for estimating fetal weight were developed by the regression method.[1-5] We also used our regression method—based formula (estimated weight = $1.73 \times BPD^3 + 23.8 \times APTD \times TTD - 217$)[6-8] until we established a new one. Although the old formula was highly accurate in normal cases, it was inadequate for the weight estimation of low birth weight infants, especially those with IUGR.[9] Fig. 4 shows the errors observed in a prospective study performed that used our previous formula.

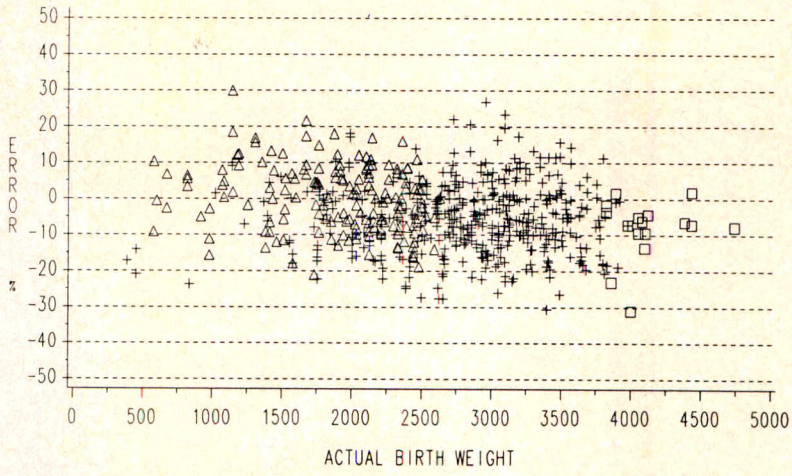

Fig. 3. Error of estimation in formula 1. (△ :LFD, + :AFD, □ :HFD). (*LFD* = Light for date; *AFD* = appropriate for date; *HFD* = heavy for date.)

3500-	47.4%	69.7%	81.6%	96.1%	3.9%
Light for date only	43.7%	76.3%	93.2%	97.9%	2.1%

It was obvious that patients weighing <2500 gm, including those with IUGR, produced heavier estimates than the actual birth weights, and the error of estimation was relatively large in these cases. Other formulas reported by Shepard et al.,[2] Walsof et al.,[1] and Hadlock et al.[3] showed the same tendency in our prospective study. The results of a prospective study that used the formula of Shepard et al. is shown in Fig. 5.

No improvement in accuracy was obtained as long as the regression method was used, because the tendency to produce heavier estimates in low birth weight infants was the result of the regression method. Because the regression model was based on patients with normal development, it is suitable for estimating normal cases but not for relatively rare abnormal cases such as IUGR.

We therefore established two new formulas that took into consideration fetal proportion, specific gravity, and volume. The results of a prospective study using these formulas showed that accuracy was significantly improved in low birth weight infants, especially those who were light for date (Tables IV, V and Fig. 3).

With our new formula, it was possible to estimate birth weights within a reasonably small range or error (15%) in nearly 90% of the cases. An error of ±10% to 15% is thought to be basically inevitable because the variance of values obtained through ultrasonic mea-

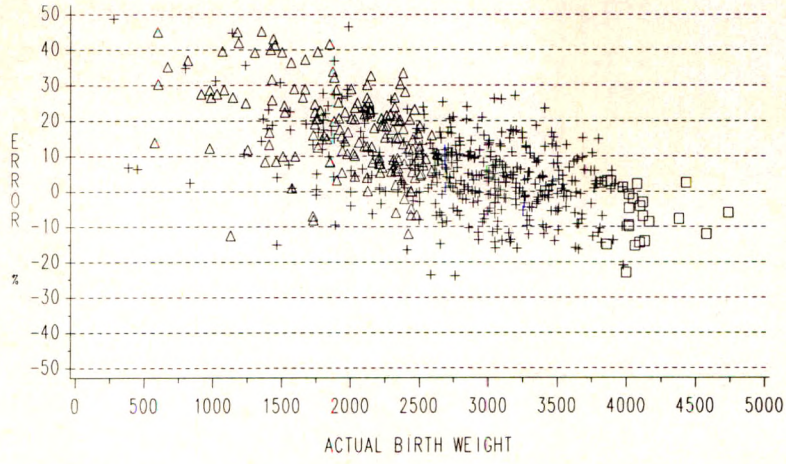

Fig. 4. Error of estimation in the formula made by the regression method: (△ :LFD, + :AFD, □ :HFD). (*LFD* = Light for date; *AFD* = appropriate for date; *HFD* = heavy for date.)

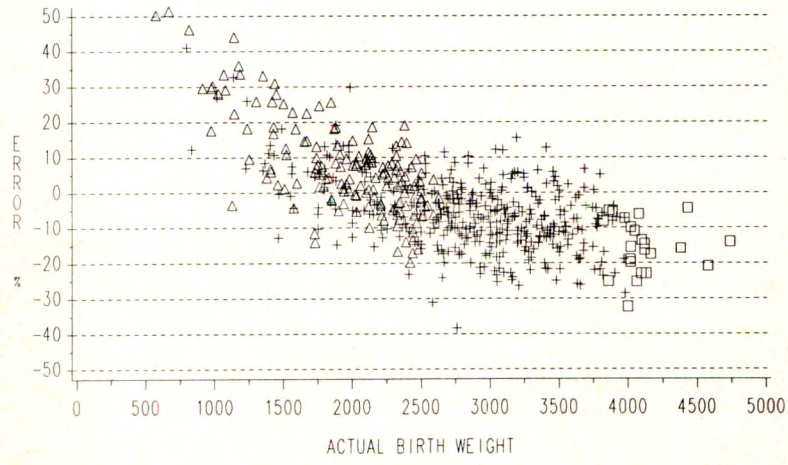

Fig. 5. Error of estimation when the formula of Shepard et al. was used. Heavier estimation was obvious in infants <2000 gm, especially those with IUGR. (△ :LFD, + :AFD, □ :HFD). (*LFD* = Light for date; *AFD* = appropriate for date; *HFD* = heavy for date.)

surements, especially those of soft tissue such as APTD and TTD, is of this magnitude.

Neonatal specific gravity is thought to change according to gestational age. Therefore, we tried to simulate the changes in specific gravity using the mean values of BPD, APTD, TTD, SL, and FL measured in 2313 cases and the mean birth weight for each gestational age on the assumption that the volume/parameter ratios were independent of gestational age. The simulation showed only slight changes in specific gravity according to gestational age. However, the improvement in accuracy achieved by correction of the formulas to adjust specific gravity according to gestational age was not significant. Furthermore, the corrected formulas were complicated (formulas 1 and 2 are multiplied by C: $C = 1.04 - 0.001 \times$ [34-gestational week]^2). The formulas with a constant specific gravity (Table III) are therefore thought to be better for practical clinical use.

In conclusion, it was confirmed that both new formulas based on fetal proportions, specific gravity, and the relationship between volumes and parameters are valuable for fetal weight estimation in low birth weight infants, especially those with IUGR, as well as normal fetuses.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Soft tissue nuchal fold in the second-trimester fetus: Standards for normal measurements compared with those in Down syndrome

Beryl R. Benacerraf, M.D., and Fredric D. Frigoletto, Jr., M.D.

Boston, Massachusetts

There are several reports describing the sonographic sign of a thickened nuchal fold for the prenatal sonographic detection of Down syndrome in the second trimester. We prospectively obtained normative data on the nuchal folds of 303 consecutive normal fetuses undergoing genetic amniocentesis between 15 and 20 weeks' gestation. The data show that the width of the nuchal fold was consistently between 1 and 5 mm regardless of gestational age (15 to 20 weeks). (Am J Obstet Gynecol 1987;157:1146-9.)

Key words: Prenatal detection, Down syndrome, nuchal fold, ultrasound

The sonographic finding of a soft tissue roll or skin thickening at the back of the fetal occiput is associated with the presence of Down syndrome in the second-trimester fetus.[1-3] In a series of 3825 consecutively scanned fetuses between 15 and 19 weeks' gestation, we found that this sign identified 42% (nine of 21 cases)

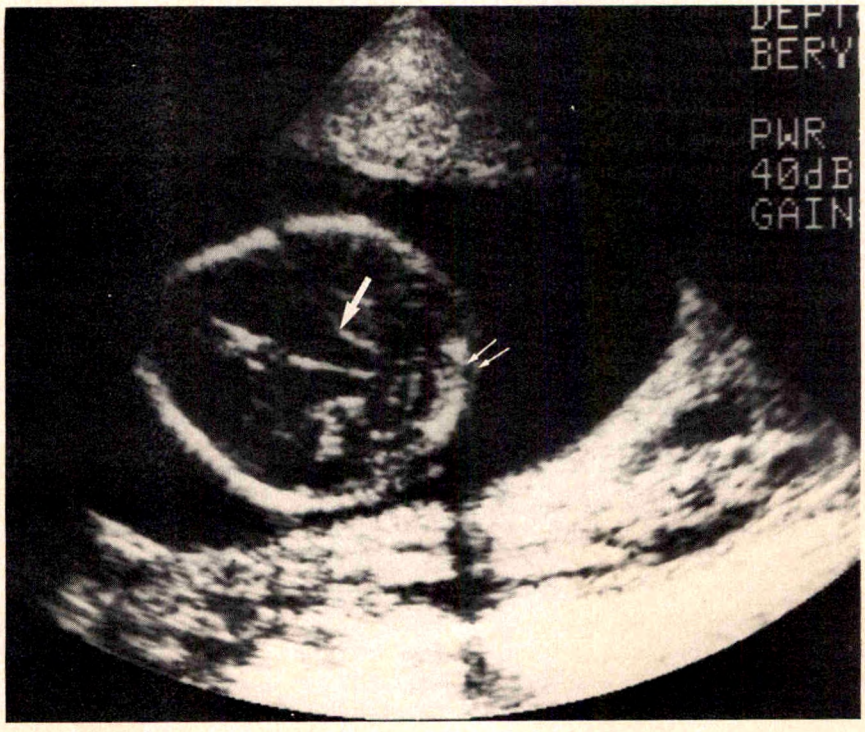

Fig. 1. Modified transverse view through the fetal head showing the thalami *(long arrow)* and the posterior fossa. The measurement of the nuchal fold is made from the outside of the occipital bone to the skin surface *(small arrows)*.

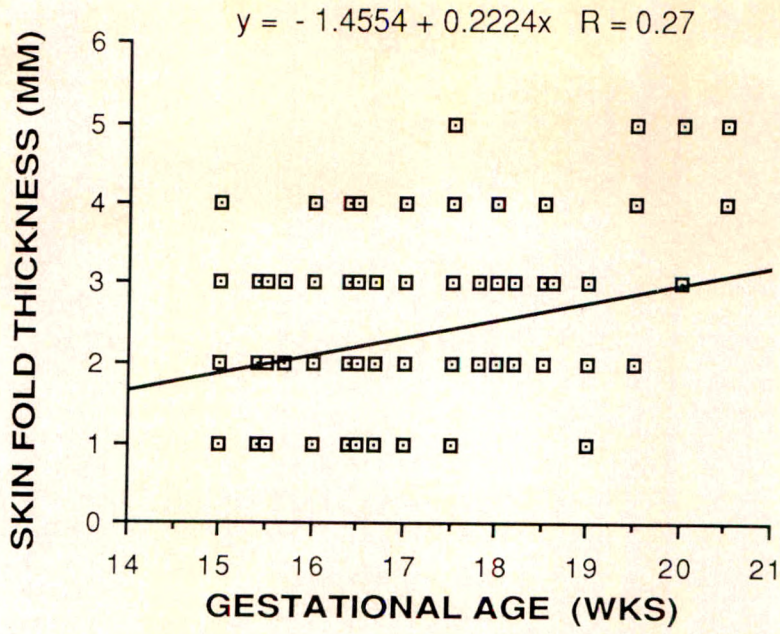

Fig. 2. Plot of gestational age versus nuchal skin fold thickness in millimeters. This demonstrates that there is no significant difference between the thickness of the skin fold in normal fetuses between 15 and 20 weeks. Note that each *square* represents several fetuses with the same measurement.

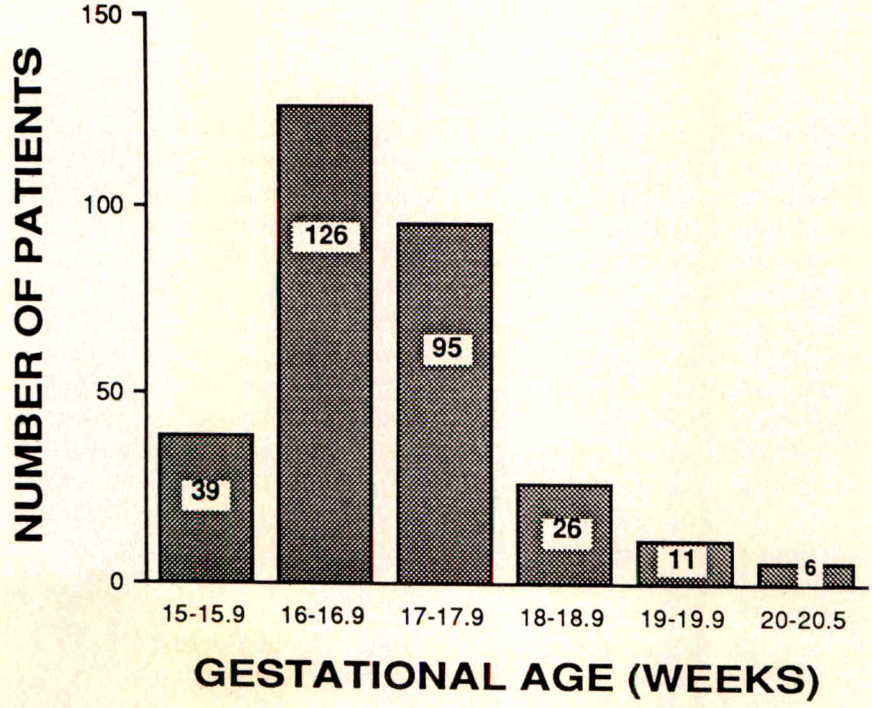

Fig. 3. Histogram showing the number of fetuses in each gestational age category within our sample of 303 consecutive fetuses at genetic amniocentesis.

of Down syndrome fetuses with a false positive rate of 0.1%.[1-3] In order to determine whether the thickness of the nuchal skin fold changed with increasing gestational age in fetuses between 15 and 20 weeks, 303 consecutive fetuses were studied at the time of amniocentesis. All were subsequently found to have normal karyotypes. The measurement of the nuchal fold was recorded prospectively in each case.

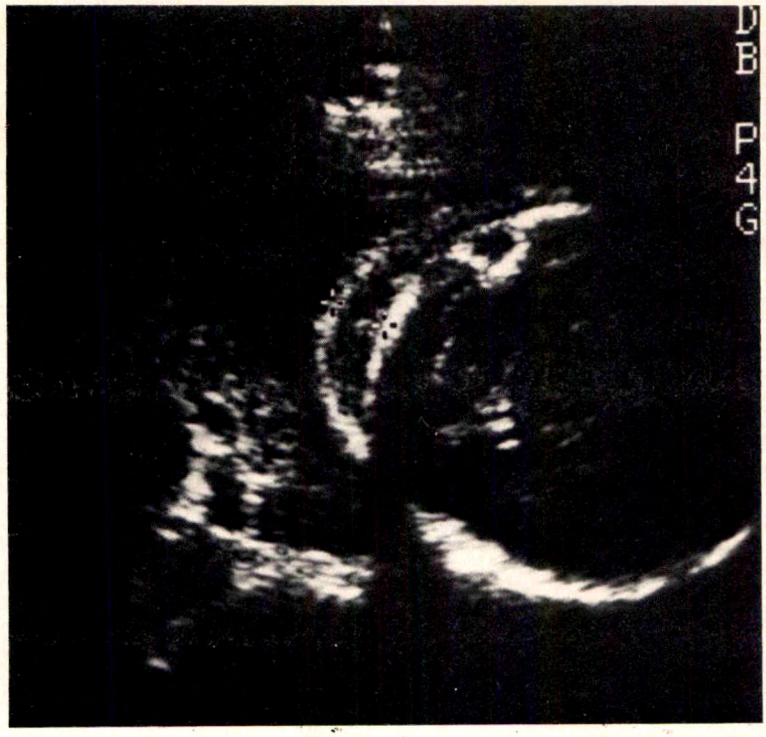

Fig. 4. Modified transverse view through the fetal head of a fetus with Down syndrome showing the measurement of the nuchal fold as made by the electronic calipers (7 mm). Please note that the posterior fossa and occipital bone are well seen in this view.

Material and methods

The soft tissues at the back of the fetal neck or occiput (nuchal fold) were measured prospectively in 303 consecutive fetuses presenting just before amniocentesis, between 15 and 20 weeks. Mothers were all at risk for Down syndrome either by being 35 years of age or more or by having a low maternal serum α-fetoprotein value. The scans were done with an Acuson 128 or ATL 300 real-time imaging system, with a 3.5 or a 3 mHz transducer, respectively. The view used to measure the back of the occiput was a modified transverse view through the fetal head, across the thalami, but angled slightly posteriorly to include the cerebellum and the occipital bone (Fig. 1). The soft tissue thickness posterior to the occipital bone was then measured, not including the bone, from the surface of the bone to the skin. Care must be taken not to measure the thickness from a plane taken below the level of the occipital bone, at the first cervical vertebra, or an incorrectly wide value will be obtained, leading to a false positive result. This assessment of the soft tissue nuchal fold was done as part of the routine measurements before the amniocentesis is performed.

Results

In these 303 fetuses measured between 15 and 20 weeks' gestation, the nuchal fold ranged between 1 and 5 mm, although most of the 5 mm measurements occurred after 19 weeks (Fig. 2). There was no significant difference in range or frequency of the measurements obtained between 15 and 20 weeks' gestation. The limited number of fetuses in the study between 19 and 20 weeks' gestation, however, do not represent conclusive data in this age group (Fig. 3). A number of attempts were made to fit these data to a curve, including linear, polynomial, and exponential algorithms, none of which yielded an r value >0.3. This strongly suggests that there are no significant differences between measurements of the nuchal fold behind the occiput between 15 and 20 weeks' gestation. None of the fetuses studied had a skin fold >5 mm.

Comment

Recent studies have shown that a nuchal fold of ≥ 6 mm in the second-trimester fetus has been associated with Down syndrome (Fig. 4). We have studied 3825 consecutive fetuses between 15 and 20 weeks' gestation undergoing genetic amniocentesis, which yielded 21 fetuses who had Down syndrome.[1-3] Nine of these 21 fetuses had a skin fold measuring ≥ 6 mm at the occiput. There were four cases where the measurement was ≥ 6 mm but the fetuses did not have Down syndrome (0.1% false positive). One of these four had an abnormal karyotype other than Down syndrome and the

others were normal. In order to further define this measurement of the nuchal skin fold in the fetus with Down syndrome, we have studied 303 consecutive normal fetuses between 15 and 20 weeks' gestation to establish the normal distribution of this measurement and to determine whether there are any differences with different gestational ages between 15 and 20 weeks' gestation. This study shows that the width of the nuchal fold was consistently between 1 and 5 mm regardless of gestational age. There were no false positive results in this study; however, because our rate of false positive results in our previous work has been 0.1%, one would extrapolate that only 0.3 fetuses would have false positive results in this group. It is therefore not surprising that no false positive nuchal fold measurements were discovered in this sample. It is of note that by far the largest number of fetuses in this study group of women undergoing genetic amniocentesis was between 15 and 19 weeks, as shown by the histogram (Fig. 3), and therefore further work would be necessary to confirm the findings on fetuses between 19 and 20 weeks' gestation because of the small numbers in that group.

It is crucial not to misuse the measurement that could lead to false positive results.[4] Too much angling in the ultrasound beam beyond the occipital bone itself can yield a spuriously wide measurement. Also it is important not to include the occipital bone in the measurement. The quantitative description of this sign has been established only for fetuses between 15 and 19 weeks' gestation and should not be extended to older fetuses until adequate studies have been done on fetuses in a specific age range.

The presence of the abnormally wide nuchal skin fold in second-trimester fetuses has made this simple measurement valuable for the sonographic detection of some fetuses with Down syndrome. The majority of Down syndrome babies are born to women who are under 35 years of age and who are not routinely candidates for amniocentesis. With the increasing use of ultrasound for a variety of indications, this sign can be very valuable for detecting candidates who would not ordinarily be offered amniocentesis but who may in fact be at high risk for having a fetus with trisomy 21.

First-trimester vaginal bleeding and the loss of chromosomally normal and abnormal conceptions

Barbara A. Strobino, Ph.D., and Judy Pantel-Silverman, M.P.H.

New York, New York

The frequency of first-trimester vaginal bleeding among 670 women with chromosomally normal fetal losses and 219 women with chromosomally abnormal losses was compared with that among 3089 women delivered at term. Vaginal bleeding early in gestation was predictive of pregnancy outcome in that moderate or heavy bleeding was associated with a fourfold risk of the loss of either chromosomally normal or abnormal conceptions. Spotting or slight bleeding was associated with a 2.7-fold risk of the loss of a chromosomally normal conception but was not associated with the loss of chromosomally abnormal conceptions when all abnormalities were categorized together. (Am J Obstet Gynecol 1987;157:1150-4.)

Key words: Vaginal bleeding, fetal loss, fetal karyotype

Vaginal bleeding, especially spotting or light bleeding, is a relatively common occurrence among women whose pregnancies proceed to term. Estimates of the frequency range from 15% to 17% when bleeding histories are obtained before delivery[1-3] or through in-person interviews after delivery.[4]

Fetal loss is almost always preceded by vaginal bleeding. There is usually bleeding before the expulsion of the products of conception but it can also occur early in gestation or intermittently throughout the pregnancy. Rates of fetal loss among women hospitalized for threatened abortion range from 35% to 50%.[5-8] However, hospitalized populations are not representative of women who experience light bleeding in the first trimester. Many cases of threatened abortion may actually be nonviable pregnancies at the time of admission. Since most fetal losses occur within 1 week of hospital admission,[6, 8] the bleeding in these cases may actually be the beginning of the expulsion process of a nonviable fetus rather than a predictor of the death of a viable fetus later in pregnancy.

Since bleeding occurs in pregnancies that end in fetal loss as well as those that proceed to term, the question remains as to whether the presence of bleeding early in pregnancy can predict subsequent fetal loss. The purpose of the analyses presented below is to determine if first-trimester vaginal bleeding that does not result in a spontaneous abortion at the time can predict fetal loss in the second trimester or later. A distinction is made between the loss of chromosomally normal and abnormal conceptions because chromosomally normal conceptions are more likely to be viable than chromosomally abnormal ones, most of which are never seen among term births.[9]

Material and methods

The data were derived from a case-control study of fetal loss carried out in New York City from 1975 through 1985 in three phases. The total case series consisted of 7872 women with a diagnosed fetal loss at <28 weeks' gestation. A total of 2346 women with fetal deaths occurring after 14 weeks' gestation were included in this analysis. Fourteen weeks was selected as a beginning point to allow for a minimum of 2 weeks to have lapsed between the onset of bleeding in the first 12 weeks of pregnancy and the fetal death.

An extensive in-person interview was administered to all women agreeing to participate. Of the 2346 eligible women, 1945 (83%) were interviewed. The questionnaires differed somewhat between the three phases but data were gathered throughout the study on the woman's obstetric, social, and medical history as well as events and exposures occurring in the current pregnancy. The vaginal bleeding histories in all three phases included date of onset, number of episodes, length of the first episode, and severity of the bleeding. The severity of the bleeding was categorized as spotting, slight, moderate, or heavy according to the woman's description of what the first episode of bleeding was like at its worst.

The products of conception were set up in tissue culture and a fetal karyotype was obtained for 979

Phase of study entrance				
1	12.8	882	20.1	349
2	17.3	1034	20.6	310
3	17.9	391	26.0	123

(50%) of the interviewed women. The second interviews of 64 women who had entered the study more than once and 26 women with incomplete bleeding histories were excluded from the sample. Thus the final sample numbered 889 cases in which a fetal karyotype was determined, 670 of which were chromosomally normal and 219 of which were chromosomally abnormal. Abnormal karyotypes included trisomy, monosomy X, triploidy, tetraploidy, and other structural chromosomal abnormalities.

The control group was selected from the prenatal facilities of the medical centers. Control selection took place throughout the 10 years of the study but was not continuous over that time so that the total control population was smaller than the total case population. Controls were selected to be similar to the cases with respect to socioeconomic status (public or private hospital facility use) and maternal age. An additional criterion for a woman to be a control was that she had to be delivered of an infant at 28 weeks' gestation or later. Most controls were approached and interviewed at a prenatal visit in the second trimester of pregnancy. Controls interviewed before 14 weeks' gestation were excluded to ensure comparable ascertainment of first-trimester bleeding for cases and controls.

Table II. Frequency of first-trimester vaginal bleeding among cases (women with fetal losses ≥14 weeks' gestation) and controls (women delivered at ≥28 weeks' gestation)

	Public patients		Private patients	
	%	n	%	n
Cases				
Normal karyotype	30.5	492	41.0	178
Abnormal karyotype	25.7	144	33.3	75
Controls	15.7	2307	21.2	782

Of the 4205 controls identified, 3676 (87%) were interviewed. The second interviews of 63 women who had entered the study more than once were excluded. Of the remaining 3613 women, 3120 (86%) were interviewed after 14 weeks and 3089 of these women had complete bleeding histories.

The characteristics of first-trimester bleeding in each of the two case groups (normal and abnormal fetal karyotypes) were compared with those of controls in separate, conditional, maximum likelihood logistic regression analyses in which cases and controls were stratified by potentially confounding variables.[10, 11] The resulting adjusted odds ratios compared the presence of first-trimester bleeding in the cases with that in the controls.

The frequency of first-trimester bleeding by various sociodemographic characteristics of the control women was examined to identify potentially confounding variables (Table I). In both public and private payment groups, the frequency of bleeding increased with maternal age and a history of previous spontaneous abortion. There was an increase in the frequency of bleeding by gravidity among public, but not private, patients. There were no consistent differences by other maternal sociodemographic characteristics, cigarette smoking, or phase of study entrance.

Results

In both public and private payment groups, the rates of first-trimester bleeding were greatest among wom-

en aborting chromosomally normal conceptions but were also increased among women aborting chromosomally abnormal conceptions when compared with rates among controls (Table II). The intensity of first-trimester bleeding was further characterized by its severity, the duration of the first episode, and the number of episodes beginning in the first trimester. Table III shows the odds ratios relating each of these characteristics of bleeding to chromosomally normal and abnormal fetal losses. These were adjusted for maternal age, phase of study entrance, number of previous spontaneous abortions, and gestation.

Both the chromosomally normal and abnormal case groups were more likely than controls to experience bleeding that was moderate or heavy, that was longer than 1 week's duration, and that consisted of multiple episodes, with odds ratios ranging from 3.6 to 4.1 for the chromosomally normal losses and from 4.9 to 8.0

for the chromosomally abnormal losses. Less intense bleeding, that is, spotting or slight, lasting <1 week, or consisting of only one episode, was more common among women with chromosomally normal losses than among controls, with odds ratios ranging from 2.1 to 3.2. There was no difference between women with chromosomally abnormal losses and controls with respect to light bleeding; odds ratios ranged from 1.1 to 1.6.

The observed associations between bleeding of either intensity and fetal loss did not vary with maternal age, reproductive history, payment status, or phase of study entrance. However, the association of moderate or heavy bleeding with both normal and abnormal fetal loss did vary by week of gestation (Table IV). The association is greatest for those losses occurring at 14 to 15 weeks and decreases thereafter. This trend is more apparent for the chromosomally normal conceptions than for the abnormal conceptions, although the odds ratios for abnormal conceptions are based on small samples in later gestations.

The association between spotting or slight bleeding and chromosomally normal loss remained relatively constant with the duration of gestation of the fetal loss. The odds ratios for chromosomally normal losses at any length of gestation did not vary greatly from the overall odds ratio of 2.7. For chromosomally abnormal losses, the odds ratios did not vary significantly from 1.0 at any length of gestation.

When a conceptus has a chromosomal abnormality, its survival is severely compromised. However, some abnormalities are compatible with survival and are seen at term among stillbirths or live births whereas others are always lethal and the fetuses never survive to term. Table V shows the odds ratios for spotting or slight first-trimester bleeding by specific groups of chromosomal abnormalities. Although the same sizes are small, there may be some variation in risk between abnormalities, raised odds ratios for triploid (odds ratio = 2.3) and trisomy 21 (odds ratio = 3.0) losses, and no association for nonviable trisomies (odds ratio = 1.1) and monosomy X (odds ratio = 0.6) losses.

Table V. Odds ratios and 95% confidence intervals relating first-trimester spotting or slight bleeding to specific chromosomal abnormalities (with controls as the reference group)

Abnormality	*n**	*Odds ratio*	*95% Confidence interval*
Viable trisomies			
21	15	3.0	1.0-8.9
13, 18, X	9	1.8	0.3-9.8
Nonviable trisomies	48	1.1	0.5-2.5
45, XO	30	0.6	0.2-2.1
Triploidy	56	2.3	1.2-4.3

*n = Number in each abnormal case group, excluding women with moderate or heavy first-trimester bleeding.

Comment

The findings of this study suggest that the presence and type of first-trimester vaginal bleeding can predict, to some extent, the outcome of the pregnancy and the characteristics of the conceptus. Moderate or heavy bleeding in the first trimester was associated with both chromosomally normal and abnormal losses in the second trimester. Even though the bleeding preceded the diagnosis of fetal loss by several weeks, it is possible that in some of these cases the conceptus was not viable at the onset of the bleeding. Ultrasound examinations were not routinely carried out to document fetal viability, especially in the early years of the study. If they had been, undoubtedly some of the first-trimester bleeding episodes would have been diagnosed as fetal deaths and the pregnancies would have been terminated. Thus our odds ratios, especially those pertaining to moderate or heavy bleeding and its relationship to fetal loss early in the second trimester, could be inflated because they include pregnancies that may not have been viable at the time of the bleeding.

Fetal viability at the time of the bleeding is less of an issue for spotting or slight bleeding since this type of bleeding is associated with a constant, increased risk of chromosomally normal loss at all lengths of gestation. Chromosomally normal conceptions have a greater potential for viability than abnormal conceptions and it is unlikely that a conceptus that was nonviable at 12 weeks would not abort until the end of the second trimester. It appears therefore that spotting or slight bleeding occurs when the conceptus is still viable, although at an increased risk of death later in pregnancy.

Light bleeding may also be increased in those women aborting conceptions with trisomy 21, a chromosomal abnormality that is compatible with survival. Although triploid conceptions never survive the perinatal period, they do occasionally come to term and, along with trisomy 21, are more likely than other chromosomally abnormal conceptions to abort late in gestation.[12]

In conclusion, the pregnancies of women who experience moderate or heavy bleeding in the first trimester are likely to end in fetal loss sometime during gestation. Spotting or slight bleeding in the first trimester indicates that a woman is at a moderately increased risk, about 2.7 times that of a woman with no bleeding, of losing a chromosomally normal conception. Additionally, it is possible that those women with chromosomally abnormal conceptions that tend to be lost late in gestation also have bleeding characteristics similar to those of women losing chromosomally normal conceptions.

Emotional responses of pregnant women to chorionic villi sampling or amniocentesis

John W. Spencer, Ph.D., and David N. Cox, Ph.D.
Burnaby, British Columbia, Canada

Seventy-four "high-risk" pregnant women interested in participating in a clinical trial comparing chorionic villi sampling and amniocentesis were initially assessed on five background measures and for anxiety, depression, hostility, and concern about abortion. The 61 women who then agreed to be randomized into the chorionic villi sampling and amniocentesis groups were assessed three additional times between 9 and 22 weeks' gestational age. Physical discomfort experienced during the diagnostic procedure was also assessed. Women in the chorionic villi sampling group underwent a reduction in anxiety up to 10 weeks earlier and reported less procedure-related discomfort than women in the amniocentesis group. The group × time interaction for depression was also significant, with women undergoing chorionic villi sampling reporting an earlier decrease in depression than women undergoing amniocentesis. No differences were found between the two groups in hostility or concern about abortion. Findings were discussed in the context of evidence linking prenatal maternal emotionality to an increased risk of obstetric complications. (AM J OBSTET GYNECOL 1987;157:1155-60.)

Key Words: Prenatal diagnosis, amniocentesis, chorionic villi sampling, maternal emotionality

Until the comparatively recent development and use of chorionic villi sampling (CVS) as a first-trimester procedure, genetic diagnosis was not possible before the midtrimester of pregnancy.[1] Amniocentesis has been the most commonly used midtrimester genetic diagnostic technique, and although the physical risks associated with amniocentesis are comparatively low (<0.5%),[2,3] the emotional distress associated with midtrimester genetic diagnosis is widely acknowledged, both in the research literature[4-6] and in anecdotal reports.[7] By comparison, the physical risks of CVS were initially reported to be greater (3% to 5%),[8] although more recent data suggest a more comparable procedure-induced loss rate in the range of 1% to 2%.[9] A direct comparison of physical risk rates between CVS and amniocentesis is complicated by (1) the higher baseline rate of spontaneous abortion during the first trimester than during the midtrimester and (2) imprecise figures for the rate of spontaneous abortion during the first trimester. Reported risk rates for CVS generally include the background rate of spontaneous abortion after that procedure, while reported risk rates for amniocentesis typically do not.

Despite the apparently greater physical risk at the time the present study was conducted, it was felt that CVS may arouse less emotional distress than amniocentesis for at least three reasons. First, the sampling occurs as early as 9 weeks' gestation, 7 weeks earlier than with amniocentesis, obviating a lengthy pretest waiting period that could arouse considerable emotional distress. Second, results after CVS are available within 1 week and in some centers within 48 hours. Results with amniocentesis usually require 3½ to 4 weeks, again imposing a longer and potentially distressing posttest waiting period. Third, elective termination can occur up to 10 weeks earlier in pregnancy after CVS than after amniocentesis. This has obvious benefits to the patient both in terms of the type of procedure (dilation and curettage versus prostaglandin injection) and the woman's personal commitment to the pregnancy and attachment to her fetus. For these reasons, emotional distress directly associated with CVS should be less than that associated with amniocentesis. Respondents in a recent study[10] confirmed that these features could enhance the acceptability of CVS for prenatal diagnosis, particularly if the risk rate was found to be equivalent to that of amniocentesis. However, this was a hypothetical situation, as none of the women in the study had actually undergone CVS. Empirical data available from the current research, although not reported here, indicate that women who underwent either CVS or amniocentesis chose CVS

when asked to project the use of genetic diagnosis to future pregnancies.[11]

Because women referred for prenatal diagnoses have high-risk pregnancies, the emotional distress evoked by these procedures may interact with and exacerbate the already elevated level of risk. There is considerable research that has implicated self-reported anxiety during pregnancy to subsequent obstetric complications,[12, 13] including somatic complaints during pregnancy[14] and labor and delivery problems.[15, 16] Hence the prenatal diagnostic procedure that evokes the least maternal emotionality for the shortest period would be the more desirable, because of a correspondingly lower potential to contribute to subsequent obstetric complications. It was expected that CVS would evoke less negative maternal emotionality than amniocentesis because it involves an earlier administration, a shorter posttest waiting period, and a less traumatic elective termination of pregnancy. The present study is an initial attempt to validate this hypothesis.

Material and methods

Seventy-four women with high-risk pregnancies of less than 11 to 12 weeks' gestational age who had been referred for prenatal diagnoses and who expressed an interest in the medical trial comparing CVS and amniocentesis were asked to participate. All were residents of British Columbia whose medical expenses were covered by the Government health-care plan, and all prenatal genetic diagnoses were conducted at Grace Hospital in Vancouver, British Columbia. Sixty-one women who agreed to continue in the study after an intake counseling session were randomized into either the CVS group (29 women) or the amniocentesis group (32 women), and dates for their prenatal tests were set at this time. All women in the study satisfied several inclusion criteria for prenatal genetic diagnosis and subject assignment was entirely random. No group assignment was made according to categories of risk. These women were asked to complete four separate sets of questionnaries during their pregnancies, although four of these women experienced spontaneous abortions and completed only the initial set. The 13 women who declined to take part in the medical trial following the intake session (nonparticipation group) completed only the initial set of questionnaires and were compared on these measures with the 61 women who agreed to participate in the trial.

Description of measures. The selection of instruments was dictated in part by the limited time available to respondents while at the hospital.

1. Background information form. This form solicited information regarding age, parity, fetal loss (a composite measure of miscarriages, stillbirths, and induced abortions), annual family income, and living arrangement of the mother and her partner.
2. Multiple Affect Adjective Checklist (MAACL). The MAACL-general is a 132-adjective checklist that measures anxiety, hostility, and depression and has been validated by a variety of settings and subjects.[17] The MAACL is psychometrically sound and correlates well with other measures of these variables, yet it can be completed by most subjects in only 5 minutes.
3. Procedure Discomfort Scale (PDS). The PDS was devised for the present investigation after a brief pilot study and was designed to compare the physical discomfort experienced by women undergoing CVS or amniocentesis. It is a Likert-type rating scale[18] from 1 to 15 that asks the respondent to rate the discomfort she experienced during her prenatal diagnostic procedure.
4. Concern about Abortion Questionnaire (CAQ). The CAQ is a form devised to compare the emotional reactions to abortion of women undergoing CVS or amniocentesis, on the basis of similar instruments that have been used at Grace Hospital to assess the psychological effects of prenatal ultrasound scanning.[19] This form asked the subject to imagine a situation in which she has learned that her fetus has a serious genetic disorder for which elective abortion may be appropriate.

Other instruments assessed the impact of prenatal diagnosis on commitment to the pregnancy. The acceptibility of CVS versus amniocentesis was also assessed among women who had undergone one of these procedures and who had knowledge of the other. These data will be presented in a subsequent report.

Procedure. After providing informed consent, the 74 subjects were asked to complete four sets of questionnaires, each requiring from 10 to 15 minutes. Three of the sets were administered at equivalent measurement points for both groups on the basis of the subjects' gestational ages, and the fourth set was administered immediately after either the CVS or the amniocentesis procedure. The repeated administrations were necessary to compare the course of maternal emotionality for women in both groups over the period of the study.

The first set (background information, MAACL, CAQ) was administered at the hospital immediately before the intake counseling session, at time 1, which occurred at 8 to 11 weeks' gestation. Thirteen subjects declined further participation in the trial and completed no further questionnaires. These women were designated as the nonparticipation group.

A second set of questionnaires (MAACL) was administered by mail at time 2, at approximately 13 to 14 weeks' gestation for women in both groups. The CVS

Table I. Means for anxiety, depression, hostility, concern about abortion, and procedure discomfort: CVS group

group had received their results,* while the amniocentesis group were still awaiting their procedures.

A third set of questionnaires (MAACL) was administered by mail at time 3, at approximately 22 weeks' gestation for women in both groups. All women in the trial had received final notification of their results.

A fourth set of questionnaires (MAACL, CAQ, PDS) was administered in the hospital at the time of the procedure for women in both groups. The CVS group completed these forms at 9 to 12 weeks' gestation, while the amniocentesis group completed these forms at 16 to 17 weeks' gestation. This administration was chronologically the second administration for the CVS group and the third administration for the amniocentesis group.

Results

The data were submitted to analyses of variance, and pairwise comparisons were conducted where appropriate. This section first reports on background variables; then findings for each of the five dependent measures are reported sequentially for the CVS and amniocentesis groups. Additional analyses comparing the CVS, amniocentesis, and nonparticipation groups on all measures were conducted at time 1 (intake). As expected, none of the main effects for group was significant at time 1.

Background variables. Results from the five background variables of age, number of children, number of fetal losses, family income, and living arrangement revealed no significant differences among the three groups.

Anxiety. Means for anxiety at each of the four measurement points are provided in Tables I and II for the CVS and amniocentesis groups, respectively. Table I reveals that the CVS groups underwent a significant reduction in anxiety from the time of procedure to time 2 (9 to 14 weeks' gestation), $F(1,27) = 13.95$, $p < 0.001$. Table II shows that the amniocentesis group did not undergo a corresponding decrease in anxiety until later, from the time of procedure to time 3 (16 to 22 weeks' gestation), $F(1,28) = 41.57$, $p < 0.001$.

Comparisons between these two groups at the three comparable measurement points confirm a significant overall difference in the course of anxiety between the two groups. The group × time interaction for anxiety was significant, $F(2,110) = 9.11$, $p < 0.001$, and Fig. 1 shows that the CVS group reported significantly less anxiety at time 2, $F(1,55) = 17.28$, $p < 0.001$.

These results clearly show that both groups of women underwent a reduction in anxiety after prenatal diagnosis, with the CVS group reporting the change as much as 8 weeks earlier than the amniocentesis group.

Depression. Tables I and II provide means for

*Data from the one woman in the study who received abnormal results were incomplete and were not included in the analyses.

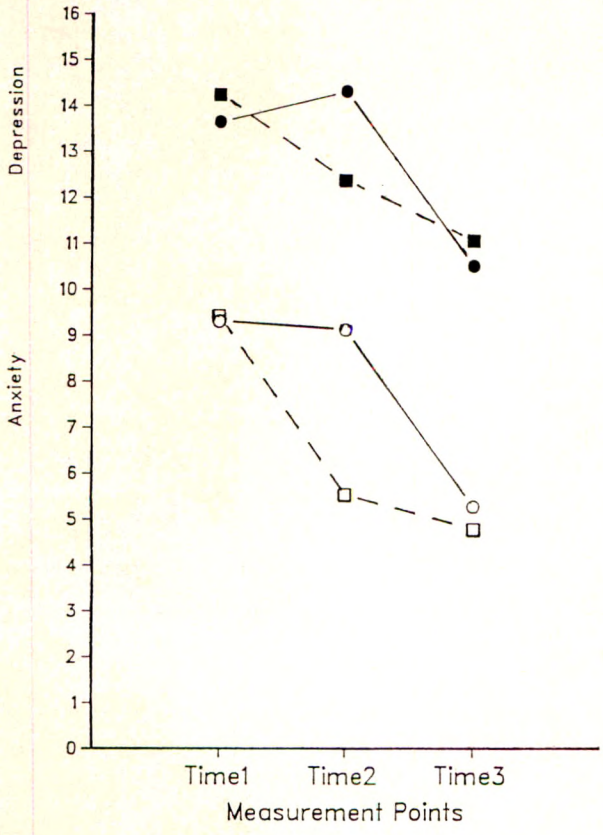

Fig. 1. Changes in anxiety and depression across measurement points for women undergoing either amniocentesis or chorionic villi sampling. ○, Amniocentesis: anxiety. □, Chorionic villi sampling: anxiety. ●, Amniocentesis: depression. ■, Chorionic villi sampling: depression.

depression at each of the four measurement points for the CVS and amniocentesis groups. The CVS group underwent its largest decrease in depression from time 2 to time 3, $F(1,27) = 5.20$, $p = 0.03$. The amniocentesis group underwent a significant decrease in depression from the time of procedure to time 3, $F(1,28) = 23.35$, $p < 0.001$.

Comparisons between the two groups at time 1, time 2, and time 3 are shown in Fig. 1. The group × time interaction was significant, $F(2,110) = 4.71$, $p < 0.01$. Again, the greatest difference between the two groups emerged at time 2, suggesting that women undergoing CVS experience a decline in depressive feelings 8 weeks earlier than women undergoing amniocentesis, but this difference falls just short of significance, $F(1,55) = 3.13$, $p = 0.08$.

Hostility. Means for hostility at the four measurement points for both groups are shown in Tables I and II. None of the changes over adjacent measurement points reached significance for either group. Comparisons between the two groups at time 1, time 2, and time 3 revealed no significance in the simple main effects or in the group × time interaction. These results suggest that feelings of hostility among subject women were unrelated to diagnostic intervention.

Procedure discomfort. Means for procedure discomfort, assessed immediately after the CVS or amniocentesis procedure, are shown in Tables I and II. The CVS group reported significantly less physical discomfort than the amniocentesis group, $F(1,55) = 14.42$, $p < 0.001$.

Concern about abortion. Tables I and II provide means for concern about abortion for the two measurement points in each of the two participating groups. No significant change over time was observed for either group, nor were the differences between the two groups significant at time 1 or the time of procedure. Because concern about abortion remained uniformly high for women in both groups before notification of diagnostic outcome, this questionnaire may have sensitized women to the stress of a potential abortion. Observations during data collection support this interpretation.

Comment

The present study indicates that emotional responses of pregnant women undergoing prenatal genetic diagnoses can vary according to the type of procedure experienced. Significant changes in reported anxiety were observed across the four measurement points for both the CVS and the amniocentesis groups. Of particular interest was the finding that the CVS women underwent a significant reduction in anxiety after prenatal testing, presumably after notification of the test results at 10 to 13 weeks. By comparison, the anxiety level among women in the amniocentesis group remained relatively high throughout the study, declining after notification of the test results at 19 to 20 weeks. Previous research into prenatal diagnosis has shown that anxiety does not abate until after the test results have been received and women are reassured that no abnormalities have been detected.[4, 20]

If the basis of the anxiety reduction is the notification of test results, women undergoing CVS will experience a decline in anxiety approximately 8 weeks earlier than women having amniocentesis. The potential importance of this difference is underscored by earlier studies that have characterized the first trimester of pregnancy as one of physical upset, emotional upheaval, and pronounced mood swings, as the pregnant women makes the initial adjustment to the change in her life.[21, 22] By contrast, the midtrimester is described as one of relative quiescence and stability, as physical symptoms subside, anxiety declines, and the initial adjustment process concludes. CVS would likely add to the emotional tumult during the first trimester, but the extent to which the increase in anxiety associated with the procedure would be detrimental is difficult to determine. The increased

stress of CVS may be offset by the early attention given the pregnancy, such as the viewing of the fetus through ultrasound.[23, 24] The fact that the entire process of first contact, prenatal testing, and notification of results can be completed within a 2-week span suggests that any CVS-induced increment in anxiety over the background level common during the first trimester may be minimal.

Women scheduled for amniocentesis typically find themselves anticipating the procedure with some apprehension. The present findings that the long waiting period before amniocentesis and subsequently for the results is one of sustained outcome apprehension are supported by anecdotal reports that this period, which extends to 20 weeks' gestation, is one of concern and agitation.[7] This period of sustained anxiety is especially disturbing in view of the finding that it is the anxiety experienced before the fifth month of pregnancy that is most predictive of obstetric complications.[25] Anxiety among women undergoing CVS would have declined by the third month, while anxiety associated with outcome apprehension among women undergoing amniocentesis would persist until the fifth month, precisely the period of the highest risk. Given that prenatal diagnostic procedures arouse anxiety, the current research indicates that CVS arouses less anxiety over a shorter period of time. In view of the research showing that significant differences in anxiety exist between complicated and uncomplicated pregnancies and that anxiety may predispose expectant mothers to obstetric complications,[12, 16, 25] the present findings that show CVS to arouse less anxiety over the long term may be of clinical importance.

The findings for reported feelings of depression among women in both groups tend to parallel those of anxiety, providing further support for the psychological desirability of CVS. The relationship between prenatal depression and obstetric outcome has not been widely investigated,[13] and the present results must be interpreted with some caution. The significant difference in reported physical discomfort associated with each procedure is of considerable interest. Clearly women undergoing CVS report far less physical discomfort that women having amniocentesis. This factor alone might be expected over time to contribute to a preference for CVS among women requiring genetic diagnosis.

Given that pregnancy is a period of psychological upheaval, particularly when there is an associated risk factor, the reduction of anxiety is of considerable value. However, prenatal diagnosis, while an important element of the technology of modern obstetric care, may have the impact of increasing the stress and anxiety that women experience. This research has demonstrated that CVS, in comparison with amniocentesis, is clearly the procedure of choice with regard to the psychological impact of genetic diagnosis in pregnancy. The implication is that as the risk rates attendant with CVS are stabilized, the desirability of the procedure should undergo a corresponding increase relative to amniocentesis.

We would like to acknowledge the support and assistance of Dr. Barbara McGillivray, Dr. Doug Wilson, and Ms. Carolyn Ganshorn during this project.

Hereditary protein C deficiency during pregnancy

Benjamin Brenner, M.D., Amos Shapira, M.D., Charles Bahari, M.D., Luis Haimovich, M.D., and Uri Seligsohn, M.D.

Tel-Aviv, Israel

Hereditary protein C, a primary hypercoagulable state, has not been previously associated with preeclamptic toxemia. A woman with previous preeclamptic toxemia and fetal deaths presented with recurrent deep vein thrombosis during her third pregnancy. Hereditary protein C was diagnosed but full heparinization followed by low-dose heparin failed to prevent preeclamptic toxemia. (Am J Obstet Gynecol 1987;157:1160-1.)

Key words: Protein C, toxemia, thrombosis

Protein C, a vitamin K–dependent plasma protein, functions in its activated form as a natural anticoagulant by inactivation of factors Va and VIIIa and by stimulation of fibrinolysis. Conversion of protein C to activated protein C is induced by a complex of thrombin and the endothelial cell receptor thrombomodulin. The function of activated protein C is enhanced by a cofactor, protein S. Recurrent thromboembolic episodes are observed in young patients with hereditary protein C deficiency. We describe here a pregnant patient with hereditary protein C deficiency who presented with recurrent deep vein thrombosis and preeclamptic toxemia.

Case report

A 22-year old woman first presented with severe preeclamptic toxemia at 26 weeks' gestation that necessitated termination of pregnancy by cesarean section. The neonate died at 10 days of hyaline membrane disease. Her second pregnancy developed normally until the thirty-sixth week when an intrauterine fetal death occurred. A repeat cesarean section was performed, during which dehiscence of the scar was noted. Autopsy revealed no fetal abnormality but extensive infarctions and calcifications were found in the placenta. Three weeks after her discharge, the patient was readmitted because of pseudotumor cerebri, which responded to treatment with dexamethasone. One month later, thrombosis of the right femoral vein was observed. Intravenous heparin was administered for 10 days followed by sodium warfarin daily for 4 months. Two months after discontinuation of therapy the patient again became pregnant and at 8 weeks' gestation another episode of thrombosis of the right femoral vein occurred. Intravenous heparin, 40,000 U/day, was given but on the eighth day thrombosis of the left femoral vein was observed. At this stage a primary hypercoagulable state was considered and explored. Antithrombin III activity (80 U/dl), protein S antigen (139 U/dl), factor VII activity (70 U/dl), and factor II activity (140 U/dl) were all within normal limits. However, protein C antigen was 55 U/dl (normal range, 68 to 130 U/dl). A family study revealed that the patient's father and three siblings also had protein C deficiency (Fig. 1). They were all asymptomatic. With continuous heparinization the acute thrombotic episodes subsided and the patient was placed on a regimen of subcutaneous heparin, 7500 U twice daily. At 34 weeks signs of preeclamptic toxemia developed: blood pressure of 160/100 mm Hg, edema, and proteinuria. Ultrasound imaging revealed moderate intrauterine growth retardation. A third cesarean section was performed at 35 weeks and a female infant weighing 1750 gm, with an Apgar score of 10 at 1 minute, was delivered. Neonatal evidence of intrauterine growth retardation was ob-

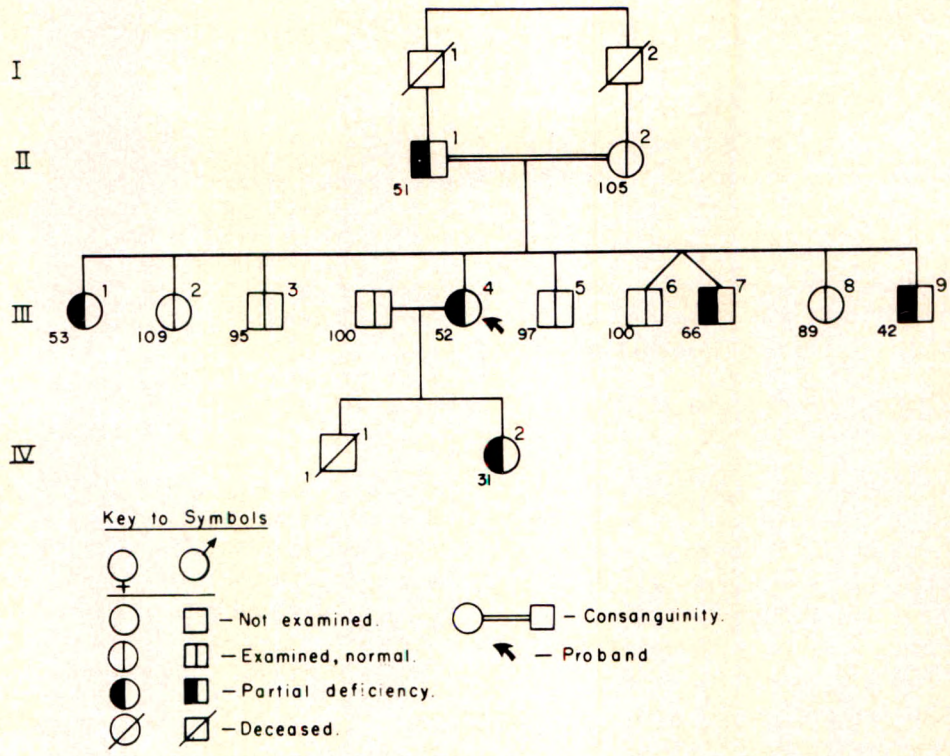

Fig. 1. Pedigree of family with members affected by hereditary protein C deficiency. *Numbers* below symbols are the observed protein C levels (units per deciliter). Note that the father and three siblings of the proband have protein C deficiency. The low level of protein C in the patient's daughter is probably related to her newborn status at examination.

served. The placenta showed extensive areas of infarction and calcification. The postoperative course was uneventful and the patient was discharged on a lifetime regimen of warfarin therapy.

Comment

Our study illustrates that patients with a hereditary hypercoagulable state are at risk of thrombosis during pregnancy. This was previously documented in patients with antithrombin III deficiency.[1] Unexplained or first-trimester thromboembolism should therefore alert the physician to examine the levels of antithrombin III, protein C, and protein S. Once the diagnosis of a hereditary hypercoagulable state is made during pregnancy or when a patient known to be affected becomes pregnant, the question of management must be addressed. During the first trimester of pregnancy oral anticoagulants are potentially teratogenic and therefore contraindicated. Furthermore, since sodium warfarin traverses the placenta, there may be a risk of fetal bleeding throughout pregnancy. Consequently, we chose to treat our patient with low-dose subcutaneous heparin throughout pregnancy. With this treatment modality thromboembolism did not recur, yet preeclamptic toxemia did develop.

It is widely accepted that placental insufficiency caused by acute atherosis and thrombosis of placental vessels may lead to intrauterine growth retardation in preeclamptic toxemia. Gilabert et al.[2] recently reported an acquired protein C deficiency and an increase in protein C inhibitor levels in patients with severe preeclamptic toxemia. Hence it is not unlikely that our patient developed preeclamptic toxemia and placental insufficiency in three successive pregnancies because of hereditary protein C deficiency. However, further observations in pregnant patients with hereditary protein C deficiency are needed in order to establish the validity of this association.

A very rare fetal malformation: The cutaneous widespread vascular hamartomatosis

Riccardo Arienzo, M.D., Cosimo S. Ricco, M.D., and Filomena Romeo, M.D.
Naples, Italy

A rare fetal malformation with a large number of vascular masses over the entire body diagnosed by ultrasound examination at 24 weeks of gestation is described. No report of this anomaly has been found in the international literature. (Am J Obstet Gynecol 1987;157:1162-3.)

Key words: Fetal malformation, vascular cutaneous hamartomatosis

The fetal vascular malformations are numerous; the more simple ones enable a normal life, but the more complicated ones do not. A case of vascular malformation with several large vascular masses detected antenatally by ultrasound examination is reported; these masses were on the skin and in the upper section of the thoracic spinal cord. No report of this anomaly has been found in the international literature, so we presume this to be the only reported case.

Case report

C. M., an 18-year-old woman, gravida 2, para 0, with one spontaneous abortion, was examined at 24 weeks of amenorrhea. Past medical history was unremarkable. The woman had not been exposed to any known teratologic agent. In September 1984 outpatient ultrasonography revealed polyhydramnios and fetal anomalies. Level 2 ultrasonography pointed out a single living fetus with several echo-free subcutaneous-cutaneous masses deforming its profile; the biggest ones were localized on the thorax, two in the front (diameter about 10 cm) and three at the back (diameter about 8 cm). Edema of the scalp also was present (Fig. 1). On November 9, 1984, a cesarean section was performed because this malformation was incompatible with life and would not have enabled vaginal delivery. A male fetus weighing 1300 gm and 30 cm long was delivered and died after a few minutes (Fig. 2).

Autopsy examination confirmed the presence of cutaneous neoformations on the thorax, abdomen, back, and limbs. These masses were of varying width and morphologic features; the smallest were of a papillary appearance, and the larger ones were exuberant, each

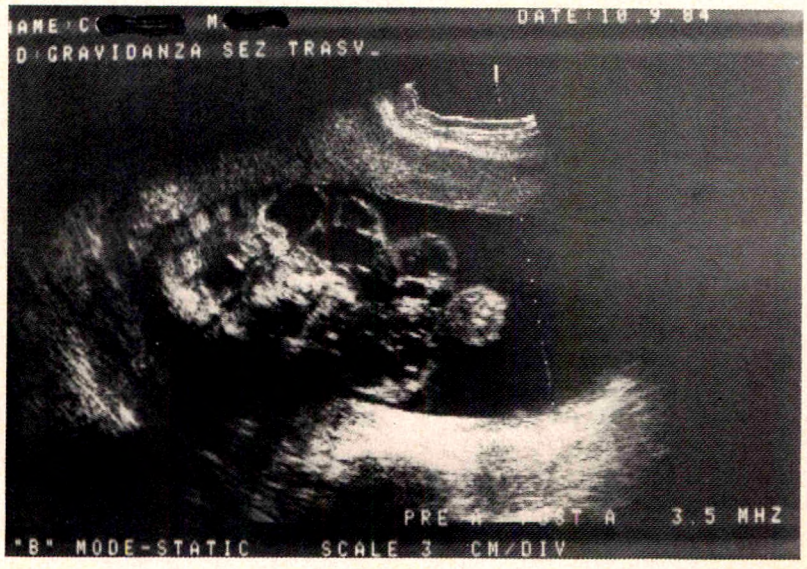

Fig. 1. Ultrasound appearance of the fetus. In this section one can see the large quantity of echo-free masses in the front and at the back.

one having a red wine–like color. The skin over the masses was taut and congested. The larger masses appeared multiloculated when cut, and each one contained bloody dark red liquid. There was one small mass in the upper region of the thoracic spinal cord. The internal organs were free of malformations. Radiologic study of the fetus did not reveal anomalies of the bone.

Microscopic study revealed that these masses were formed by capillary-like vessels with cavernous dilatation and congestion. The dermis and subcutaneous tissues were edematous with beginning sclerosis. The pathologic diagnosis was cutaneous widespread vascular hamartomatosis.

Comment

This case is unique because of the widespread cutaneous lesions with only one in a medullary location, the exuberance of the lesions, and the absence of associated malformations. Under the microscope these masses look like cavernous hemangiomas, but, unlike this condition, they are numerous, they are not associated with mesodermic dysplasia, like Maffucci's syndrome, and their location is not splanchnic, as in "blue rubber bleb nevus syndrome." Moreover, these masses differ from venous ectasia (nevus flammeus, nevus vinosus) and associated syndromes (Sturge-Weber syndrome and others) because they are characterized by proliferation of newly formed vessels instead of ectatic vessels. Finally, another pecularity of this case is the isolated involvement of a very small part of the spinal cord.

Updated pregnancy rates for the Today contraceptive sponge

David A. Edelman, Ph.D., and Barbara B. North, Ph.D., M.D.
Chapel Hill, North Carolina, and Laguna Niguel, California

Pregnancy rates (method and user) were evaluated for 2245 women who participated in the phase III clinical trials of the Today contraceptive sponge. User and method pregnancy rates were similar for women of different ages and parities. The 1-year method and user pregnancy rates (life table per 100 women) were 8.2 and 5.6, respectively. (AM J OBSTET GYNECOL 1987;157:1164-5.)

Key words: Contraceptive sponge, pregnancy rates, parity

The Today contraceptive sponge (VLI Corporation, Irvine, California) first became available to consumers in the United States in 1983. Since that time it has been approved for use and is being sold in a number of other countries including Korea, Sweden, Switzerland, and the United Kingdom. Phase III clinical trials of the Today sponge were started in 1979, and since that time data on 2245 women have been accumulated. Pregnancy data from studies conducted in the United States, the United Kingdom, and Yugoslavia have been published previously[1-3] and account for only about 55% of the women included in the trials. This communication presents pregnancy rate data from the worldwide clinical trials of the contraceptive sponge and includes data from previously published studies.[1-3] Since the effectiveness of vaginal contraceptives depends on whether they are correctly and consistently used, pregnancy rates were evaluated according to whether they were a result of failure of the user to use the sponge as directed (user failure) or because the method failed even though the sponge was correctly used (method failure).

Methods and material

The Today sponge is made of proprietary polyurethane and contains 1 gm of the spermicide nonoxynol 9, as well as small amounts of preservatives (citric, sorbic, and benzoic acids) that help to maintain its pH at about 4 to 5. The sponge is 2.5 cm thick and has a diameter of 5.5 cm. About 125 mg of nonoxynol 9 is eluted from the sponge during a 24-hour use period. The sponge is inserted into the vagina at any time up to 24 hours before intercourse. Repeated intercourse may occur with the sponge in place. The sponge is left in place for at least 6 hours after intercourse. The maximum recommended use time is 24 hours. Use of the sponge during menstruation is not recommended.

Table I. Cumulative 12-month life-table method and user pregnancy rates (per 100 women)

	No. of women	*Pregnancy rate*	
		Method (mean ± SEM)	*User (mean ± SEM)*
All clinics	2042	8.2 ± 0.8	5.6 ± 0.7
Nulliparous women	1088	7.8 ± 1.0	5.3 ± 0.9
Multiparous women	954	8.7 ± 1.2	5.6 ± 1.0
Age (yr)			
<19	133	2.5 ± 1.4	4.5 ± 3.7
19-26	941	9.0 ± 1.3	6.2 ± 1.1
27-40	933	7.2 ± 1.1	5.0 ± 0.9
>40	35	—†	—†

*Women not followed up were excluded from the table.
†Too few women for calculation of reliable life-table rate.

Pregnancy rates are based on data gathered on 2245 women from 26 clinics (Bangladesh, two; Canada, one; Israel, one; Sweden, one; Switzerland, four; Taiwan, one; United Kingdom, one; United States, 13; Yugoslavia, two). No follow-up data or incomplete records were obtained for 9.0% of the subjects. All pregnancies were classified as either user or method failures on the basis of information in the case report forms and coital logs (completed by only a subset of subjects) and from comments provided by the women and their physicians. Insufficient information was provided to classify 13 (6.7%) of the 172 pregnancies (103 method, 69 user) occurring during the 12-month follow-up period. These pregnancies were classified arbitrarily and conservatively as method failures. Pregnancy rates were computed by use of life-table methods that provide estimates of the risk of pregnancy as a function of time. Pregnancy rates were compared by means of the log rank test statistic. All of the analyses are based on the pooled data from the clinics since there were too few subjects for evaluation in all but a few clinics.

Results

The overall, cumulative 12-month pregnancy rate was 13.3 per 100 women (method, 8.2; user, 5.6). User and method pregnancy rates are given in Table I. Neither method nor user pregnancy rates depended on parity (nulliparous versus parous) or age of the women ($p > 0.10$). The same holds true for the combined pregnancy rate. At seven of the 13 clinics in the United States, 88 women volunteered to participate in the studies for a second year. The overall, cumulative pregnancy rate for these women during their second year of use was 3.4 per 100 women.

The lost-to-follow-up rates varied from clinic to clinic. However, there was no relationship between the pregnancy rates (user, method, overall) and lost-to-follow-up rates ($p > 0.10$). The cumulative 12-month pregnancy rates (user, method, overall) were not similar across clinics ($p < 0.05$).

Pregnancy rates (user, method, overall) based on the data from clinics that had women complete coital logs were similar ($p > 0.10$) for women who completed the coital logs and for those who did not. The principal use of these logs was to evaluate patterns of sponge use and provided no useful data for the analyses of pregnancy rates.

Comment

The presentation of method pregnancy rates is important so that women may assess their risk of pregnancy if they use the sponge consistently and correctly according to the user directions. Overall pregnancy rates do not provide this information.

The data presented in this paper include the results of previously published studies from the United States,[1] the United Kingdom,[2] and Yugoslavia.[3] The data from the study of 721 subjects conducted in the United States at 13 clinics[1] showed that the cumulative 12-month overall pregnancy rate was related to parity but not age. The report did not provide data on method or user pregnancy rates or on the pregnancy rates reported at the individual clinics. The study conducted in the United Kingdom[2] gave higher overall pregnancy rates than did the study in the United States but no significant differences in the overall pregnancy rates for parous and nulliparous sponge users were reported. No data on either method or user pregnancy rates were reported. The study included only 126 sponge users. The Yugoslavian study[3] included 403 subjects from two clinics and reported no significant differences between the cumulative 12-month method pregnancy rates of parous and nulliparous sponge users. No data were provided on user pregnancy rates.

If the 13 pregnancies for which there was insufficient information to classify as either method or user failures had been apportioned between method and user failures, lower method and higher user pregnancy rates would have been obtained. Failure to adequately wet the sponge before insertion may be one factor responsible for some of the method failures. When the phase III trials were initiated in 1979, the importance of adequately wetting the sponge to activate the release of spermicide was not fully appreciated. As experience was gained with use of the sponge more emphasis has been placed on adequate wetting before its insertion. This seems to have had a positive effect on the incidence of reported pregnancy.

The continued evaluation of pregnancy rates associated with use of the Today contraceptive sponge shows that it provides women with an adequate level of protection against pregnancy regardless of their age or parity.

Treatment of nonmetastatic gestational trophoblastic disease with oral methotrexate

James F. Barter, M.D., Seng Jaw Soong, Ph.D., Kenneth D. Hatch, M.D., James W. Orr, Jr., M.D., Edward C. Partridge, M.D., J. Maxwell Austin, Jr., M.D., and Hugh M. Shingleton, M.D.

Birmingham, Alabama

Fifteen patients with nonmetastatic gestational trophoblastic disease were treated solely with methotrexate given orally rather than intramuscularly. Remission, defined as a β-human chorionic gonadotropin titer of <5 mIU/ml for 3 consecutive weeks, was attained in 13 (87%) of the 15 patients. Level of toxicity was acceptable. Patient comfort, convenience, and less time off work and in the physician's office are significant advantages to this efficacious, well-tolerated method of therapy. (AM J OBSTET GYNECOL 1987; 157:1166-8.)

Key words: Gestational trophoblastic disease, oral methotrexate

The treatment of gestational trophoblastic disease has advanced significantly since the initial report of Li et al.[1] describing the efficacy of methotrexate. Today, patients with the nonmetastatic form have remission rates of 100% and low (2.1%) relapse rates.[2] Traditional therapies for nonmetastatic gestational trophoblastic disease include a 5-day course of low-dose intramuscular methotrexate, a 5-day course of daily intravenous dactinomycin (actinomycin D),[3] or an 8-day regimen alternating high-dose intramuscular methotrexate with folinic acid rescue.[4] These regimens require hospitalization or daily visits to the physician's office.

Recent investigations into the treatment of nonmetastatic gestational trophoblastic disease concern regimens that are convenient, cost-effective, easily administered, minimally toxic, and yet maintain the established, excellent cure rate. Although the initial success of Li et al. in treating gestational trophoblastic disease included the use of oral methotrexate,[1] there has been very little subsequent interest in this route of administration. This retrospective report details our experience with only oral methotrexate to treat patients with nonmetastatic gestational trophoblastic disease.

Material and methods

Records of all patients with any form of gestational trophoblastic disease treated at the University of Alabama Medical Center in Birmingham from 1973 to 1984 were reviewed. Fifteen patients with nonmetastatic gestational trophoblastic disease were treated with methotrexate by mouth as their only means of therapy. The standard dose of 0.4 mg/kg with a maximum of 25 mg was given once daily for 5 consecutive days with a 9-day interval before the next course. All patients received one course of therapy after the first β-human chorionic gonadotropin (β-hCG) titer of <5 mIU/ml. Patients medicated themselves with the daily prescribed afternoon dose of methotrexate. They were seen by physicians and hematologic and hepatic laboratory studies were obtained on the first and fourth treatment days as indicated. Most of the patients were treated by their local physicians in consultation with gynecologic oncologists at this institution. No patient was hospitalized for treatment. Doses and treatment intervals were modified according to level of toxicity.

Results

The median age of the patients was 22½ years. Chemotherapy was started in one patient who had a choriocarcinoma in the initial endometrial curettage specimen. The other 14 patients had evacuated molar pregnancies evacuated, and subsequent stabilization or elevation of their β-hCG titers mandated a work-up and chemotherapy. Pretreatment evaluation included chest x-ray films, brain scan, or computed tomography and liver scan or an abdominal computed tomography scan.

Thirteen of the 15 patients (87%) receiving oral methotrexate as their only form of chemotherapy attained biochemical remission. The median number of chemotherapy courses was 2.88 (range two to five). Seven of the 15 patients experienced mucositis, but only

From the Division of Gynecologic Oncology, Department of Obstetrics and Gynecology and Comprehensive Care Center, University of Alabama Medical Center.
Received for publication February 9, 1987; revised May 11, 1987; accepted June 25, 1987.
Reprint requests: James F. Barter, M.D., Lombardi Cancer Center, Division of Gynecologic Oncology, Georgetown University Medical Center, 3800 Reservoir Road, N.W., Washington, DC 20007.

three needed a dose reduction. No patient experienced granulocytopenia (<3000 white cells/mm³), thrombocytopenia (<100,000 platelets/mm³), or hepatic toxicity (any liver function test greater than two times normal). The two patients with resistant gestational trophoblastic disease were cured with 5-day courses of actinomycin D; each needed and three courses, respectively.

The median β-hCG at the start of oral methotrexate was 2745 mIU/ml (range 48 to 58,000 mIU/ml). There were no relapses, which were defined as recurrent gestational trophoblastic disease within 1 year of the first β-hCG titer of <5 mIU/ml. The median follow-up is 5.3 years (range 1.96 to 11.8 years).

Comment

Treatment of nonmetastatic gestational trophoblastic disease with conventional methods has an excellent cure rate, and yet efforts have been made to decrease toxicity and increase patient convenience and cost-effectiveness. In 1967 Hammond et al.[5] reported a sustained remission rate of 93% with the use of intramuscular methotrexate. In 1975 Osathanondh et al.[6] revealed a 94% remission rate using a 5-day course of intravenous actinomycin D. Unfortunately, almost one half of the patients treated with actinomycin developed alopecia.[7] More recent information by Smith et al.[8] revealed an overall remission rate of 82% in the treatment of nonmetastatic gestational trophoblastic disease with intramuscular methotrexate; 7.7% of patients required a change because of resistance to methotrexate, and 10.3% needed a change because of methotrexate toxicity. Using high-dose intramuscular methotrexate with folinic acid rescue, the same group of investigators achieved a remission rate of only 72.6%, although Berkowitz et al.[4] showed an overall sustained remission rate of 89% using a similar regimen. Toxicity rarely necessitated a change of therapy when using intramuscular methotrexate with folinic acid rescue[4,8]; however, these patients are often hospitalized during the days of treatment.

Alternative routes of therapy include the recent prospective report by Petrilli et al.[9] from the Gynecologic Oncology Group that showed a 94% remission rate with the use of biweekly outpatient pulse actinomycin D in patients with nonmetastatic gestational trophoblastic disease. However, in an earlier report, Schlaerth et al.[10] reported only a 75% remission rate with similar regimen of pulse actinomycin D therapy. Nausea and vomiting were the chief toxicities but were felt to be acceptable in frequency and severity. Wong et al.[11] reported a 100% remission rate with oral VP16 for gestational trophoblastic disease, but all patients had nausea and 92% had total alopecia.

Our remission rate of 87% with only oral methotrexate is comparable with those obtained with intramuscular methotrexate, intramuscular methotrexate with folinic acid rescue, and pulse actinomycin D. The toxicities associated with oral methotrexate are mild, and the overall recurrence rate of 0% compares favorably with the 6.3% and 1.2% rates for intramuscular methotrexate and methotrexate with folinic acid rescue, respectively.[4,8]

Oral methotrexate use in malignancies other than gestational trophoblastic disease has been studied, but different doses and periods of treatment are used. Henderson et al.[12] demonstrated that low doses of methotrexate are completely absorbed from the gastrointestinal tract, whereas higher doses have a more prolonged and incomplete absorption phase. Significant interindividual variability in methotrexate levels after oral administration has been demonstrated,[13] but this was in the prolonged 1- or 2-year maintenance phase of leukemia treatment. Mucositis may interfere with the absorption of oral methotrexate, although this did not appear to have clinical significance in our patients.

We recommend that methotrexate be given as a single dose in the late afternoon. Subdivided doses should not be given, since they cause higher prolonged serum levels and could result in more toxicity.[14] In addition, methotrexate should be given 1 hour before or 2 hours after meals to ensure absorption. Finally, methotrexate should not be administered with salicylates or sulfa drugs, since these may displace the methotrexate from plasma proteins, resulting in higher serum concentrations.[15]

Oral methotrexate has the significant advantages of patient convenience and comfort, decreased cost, and less interference with the patient's daily work schedule. Compared with other regimens, the remission and recurrence rates are excellent and the drug is very well tolerated. Patients who do not improve with oral methotrexate are readily cured with actinomycin D and are not in jeopardy of having resistant disease. A future report will describe our experience treating patients with nonmetastatic gestational trophoblastic disease with one of the more traditional routes followed by oral methotrexate cycles. Controlled prospective studies are needed to provide further information regarding this convenient and simple route of therapy.

Sonographic diagnosis of a bladder polyp

Lars P. Jensen, M.D., and Charles M. Lynne, M.D.
Miami, Florida

Presented is a case of a bladder polyp diagnosed by ultrasound and removed by transurethral resection.
(Am J Obstet Gynecol 1987;157:1168-9.)

Key words: Bladder, ultrasound, polyp

Inflammatory polyps of the bladder are not uncommon, but are usually diagnosed at the time of cystoscopy for recurrent urinary complaints.

Case report

A 44-year-old woman, gravida 4, para 2-0-0-2, presented for follow-up 3 months after a uterine curettage done outside the United States and performed because of a blighted ovum. Physical examination results were within normal limits, but on inspection of the original ultrasound pictures a polyplike structure was noted in the bladder (Fig. 1). The patient was totally asymptomatic but gave a history of previous bladder infections. She was referred to a urologist, who confirmed the finding. A transurethral resection of the polyp was performed. The polyp measured 1.3 by 0.7 by 0.5 cm and on histologic examination was diagnosed as severe glandular cystitis.

Comment

In long-standing chronic inflammation, small areas of bladder mucosa may become buried, causing small cystic inclusions. Occasionally the epithelium undergoes metaplasia and begins to become columnar mucus secreting, giving rise to glandular cystitis.[1]

The initial cystoscopic diagnosis of a malignancy was incorrect in this case. Had it been correct and if the malignancy was missed, the final result might have been very different.

Sonography has been used increasingly as a noninvasive preliminary diagnostic tool to investigate causes of hematuria, dysuria, and voiding difficulties in children.[2] In adults, however, radiology and cystoscopy have remained the diagnostic modalities of choice. That the sonographic diagnosis of an inflammatory bladder polyp is rare is supported by the absence of reports in the literature. Benecerraf et al.[3] reported on four bladder tumors found incidentally in 3000 pelvic ultrasound studies. However, all of these were malignant tumors.

In routine gynecologic sonography, a full bladder is used to enable one to view the pelvic organs more clearly. It may therefore behoove the examiner, as illustrated by this case, to use this opportunity to examine

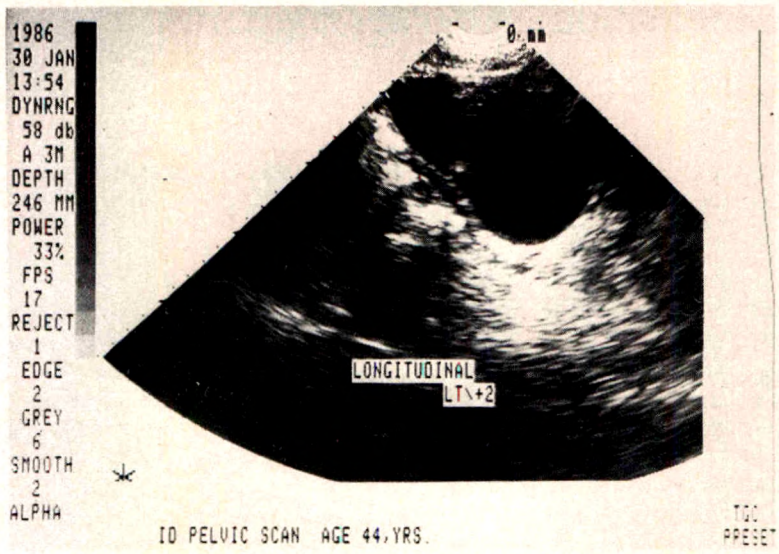

Fig. 1. Longitudinal view of bladder showing polyp posteriorly.

the bladder systematically before proceeding to the gynecologic examination, not merely to use the bladder as a "window." Conversely, however, it should be stressed that ultrasound should not be used as a substitute for cystoscopy in the diagnosis of bladder tumors, as proved tumors have been missed by this modality.[4]

Sonographic evaluation of the cervix during ovulation induction

Lyndon M. Hill, M.D., Carolyn B. Coulam, M.D., Sandra L. Kislak, R.T., R.D.M.S., Carol S. Peterson, R.D.M.S., and Cynthia J. Runco, R.D.M.S.

Pittsburgh, Pennsylvania

With the induction of ovulation, clomiphene citrate and human menopausal gonadotropin have the potential to stimulate the endocervical glands. We have found that the degree of mucus production can occasionally be quite large and hence is detectable by sonographic evaluation as an anechoic cervical mass. The incidence of this specific ultrasonic finding was found to be approximately 5%. This physiologic process should be differentiated from disease states affecting the cervix. (Am J Obstet Gynecol 1987;157:1170-4.)

Key words: Ultrasound, cervix, ovulation induction

Historically, ovulation has been monitored by clinical parameters. With the development of radioimmunoassays, the hormonal assessment of ovulation became possible. During the 1970s, the development of high-resolution ultrasonography permitted the endocrinologist to: (1) observe the ovary during the menstrual cycle, (2) identify the dominant follicle, and (3) determine the probable time of ovulation.[1-3] In vitro fertilization programs have come to rely heavily on ultrasound examination to not only provide a reliable measure of follicular growth but also to direct transabdominal or transvaginal egg retrieval.[4, 5]

Ovulation-inducing agents (clomiphene citrate and human menopausal gonadotropin) also play a key role in in vitro fertilization programs by increasing the number of preovulatory follicles available for retrieval. These drugs may indirectly effect the cervix by altering the concentration of estrogen and progestogen.

We present our findings relative to the sonographic evaluation of the cervix during the induction of ovulation with either clomiphene citrate or human menopausal gonadotropin.

Material and methods

One hundred two consecutive patients receiving clomiphene citrate and 344 patients receiving human menopausal gonadotropin for ovulation induction were studied.

Ultrasound examinations were performed with real-time equipment with a 3.5 MHz transducer. A moderately full bladder was required as the acoustic window through which normal pelvic anatomy could be viewed.

Results

Table I outlines the number of patients taking either clomiphene citrate or human menopausal gonadotropin who had sonographically detectable cervical mucus during an induced cycle. Clomiphene citrate and human menopausal gonadotropin appear to have a comparable effect on endocervical gland production: 4.9% of patients in each group had sonographically detectable cervical mucus.

The degree of bladder filling plays a critical role in the prevalence rate obtained. If the bladder is overly distended, the cervix is compressed and cervical mucus is not apparent (Fig. 1, *A*). After partial voiding, the same patient may be found to have a significant amount of endocervical mucus (Fig. 1, *B*).

The amount of cervical mucus present on sonographic evaluation may vary from several small adjacent anechoic areas to a single large mass (Figs. 2, and 3, *A* and *B*).

Table II outlines the history, diagnosis, therapy, and estradiol levels of three study patients on human menopausal gonadotropin. Sonographically, the degree of cervical mucus production was unrelated to the levels of estradiol.

Comment

Histologically, the cervix is composed of a complicated system of longitudinal, oblique, and transverse mucosal folds that extend into the subadjacent connective tissue.

In the early follicular phase of a normal cycle, the endocervical glands are short and have a relatively simple pattern. However, in the late follicular phase, the

glands become tortuous; they invaginate further into the cervical connective tissue, the columnar epithelium achieves its maximal height, and mucus production is at its peak. Vascularization of the cervix is improved, and the texture of the cervical connective tissue becomes looser. Anatomically, the external cervical os widens during the menstrual cycle and achieves its maximal width immediately before ovulation.

The appearance of cervical mucus has been scored by Insler et al.[6] This system takes into consideration the quantitative and qualitative changes that occur in cervical mucus during different phases of the menstrual cycle. Thus the quantity of mucus, the presence or absence of ferning, spinnbarkeit, and the appearance of the cervix are assessed.

become atretic after the selection of a dominant follicle continue to grow and mature. Although ovulation rates are reported to be between 50% and 80% while taking clomiphene citrate, significantly lower rates of conception are achieved.[7] Thick tenacious mucus caused by the antiestrogenic effect of clomiphene has been proposed by several authors as the etiologic mechanism for this finding.[8] However, Hancock and Oakley[9] found that this effect disappeared within 1 week after the medication was discontinued. Gysler et al.[10] discovered additional infertility factors in 159 of 182 patients (87.4%) who ovulated but did not conceive while taking clomiphene citrate. The authors also stated that better cervical mucus was present in the patients receiving clomiphene citrate than in the general population of infertility patients referred to their clinic. O'Herlihy et al.[11] have also suggested that the antiestrogenic effects of clomiphene have relatively little effect on the cervical mucus score.

Stimulation of the cervical glands with human menopausal gonadotropin is caused by the estrogen produced by the maturing follicles. Since a greater number of follicles are usually stimulated with human menopausal gonadotropin than with clomiphene, the levels of estrogen achieved during human menopausal gonadotropin–induced cycles are frequently higher. Therefore one would anticipate a greater stimulation of the cervical glands with human menopausal gonadotropin than with clomiphene citrate.

The reported effects of ovulation-inducing medications on cervical gland production have failed to date to take into consideration the target organ. Sanborn et al.[12] have found specific estrogen-binding proteins in the human cervix. Clomiphene citrate may, for example, act locally to block receptors in the endocervical epithelium. The quantity of receptors (and blockers), as well as their binding properties, may vary from patient to patient and cycle to cycle, thereby producing the variable effects noted by different groups. Our findings add credence to this assumption. A noticeable amount of mucus was not apparent on sonographic examination until after 5 days of clomiphene or human

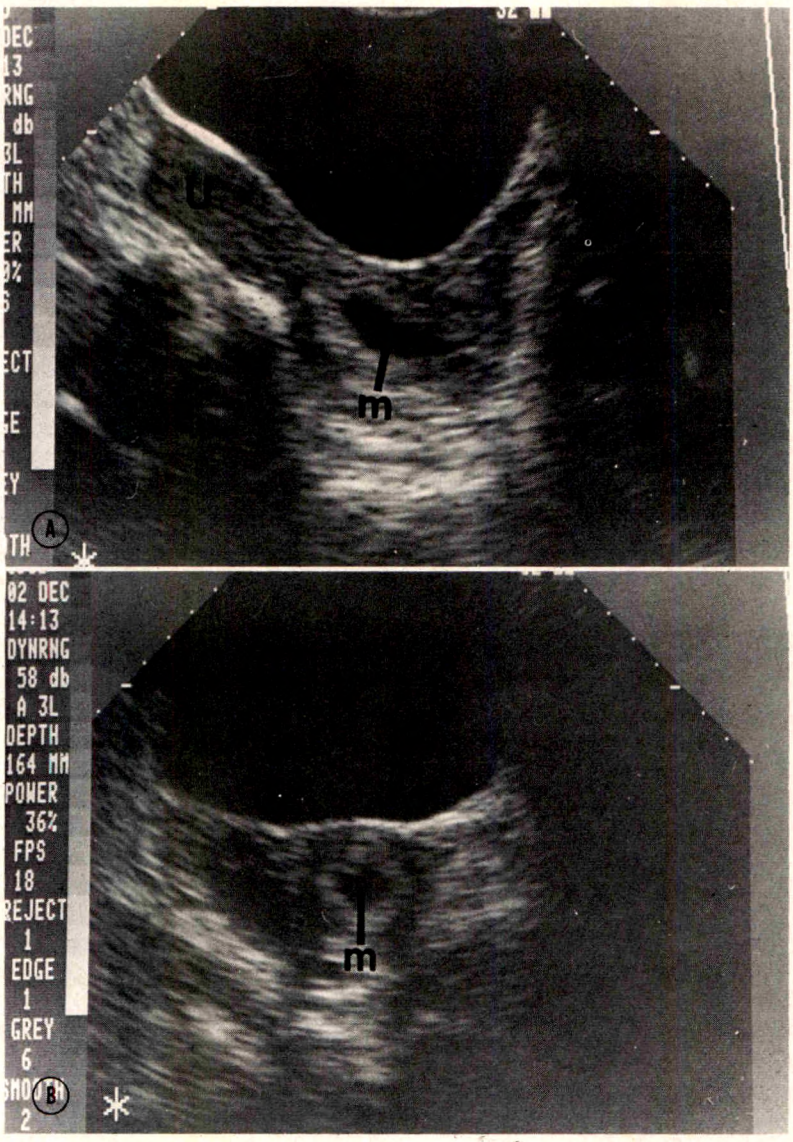

Fig. 3. Sonographic evaluation of the cervix after human menopausal gonadotropin. **A,** Longitudinal scan. Mucus accumulation in the cervix is readily apparent. (u = Uterus; m = mucus.) **B,** Transverse scan of the cervix. (m = Mucus.)

menopausal gonadotropin. Although this suggests an association with increased estrogen production, the presence or absence of ultrasonically detectable cervical mucus was not directly related to a specific estrogen level obtained in a given cycle (Table I). Consequently, a patient may have several induced cycles without any noticeable effect on the cervix followed by a cycle in which the retention of cervical mucus is particularly prominent. We have found that the retention of cervical mucus may last from one to 10 cycles and in some instances can be quite large (Fig. 3, *A* and *B*).

The practice of ultrasonographic monitoring during ovulation induction has increased. As a result, the sonographer should be aware of not only the follicular changes associated with stimulated cycles but also with the possibility of the cervical changes previously noted. The recognition of the iatrogenic cause of the latter findings will alleviate not only the patient and physician's anxiety concerning the presence of a cervical mass, but it will also prevent further unnecessary testing.

A prospective randomized study of the aggressive management of early labor

Gary R. Cohen, M.D., William F. O'Brien, M.D., Lloyd Lewis, M.D., and Robert A. Knuppel, M.D., M.P.H.

Tampa, Florida

The aggressive management of early labor has been suggested as a means to lower the cesarean section rate for dystocia. The aim of our study was to prospectively evaluate a protocol of early intervention in primigravid women with infrequent uterine contractions during early labor in relation to the course of labor, the cesarean section rate, and the perinatal morbidity. In our population the active management of labor did not alter the mode of delivery or the perinatal outcome. Furthermore, the course and duration of labor were not significantly different between the management and control groups. (Am J Obstet Gynecol 1987;157:1174-7.)

Key words: Labor, active management; dystocia; cesarean section

The rate of cesarean birth has exceeded 20% nationally. The largest increase has been in the group characterized by the diagnosis of dystocia. Approximately 50% of all primary cesarean sections are performed because of dystocia while the remainder are done because of malpresentation, fetal distress, or medical indications.[1] This dramatic rise in operative delivery rate in the United States has not been paralleled in other countries.[2-4] The experience in Ireland has been a stable incidence rate with the incidence of dystocia being one tenth that of the United States.[5, 6] This difference has been attributed to the philosophy of active management of labor.[5, 7, 8] The purpose of this study was to assess an aggressive approach to early labor in a prospective randomized fashion to determine if such treatment could alter the cesarean birth rate in an American hospital serving a primarily indigent population.

Material and methods

One hundred fifty primigravid patients who presented to the obstetric suite at Tampa General Hospital between September 1, 1985, and June 20, 1986, were entered into the study protocol. Eligible patients were treated according to the study protocol as approved by the institutional review boards of both the hospital and the University of South Florida College of Medicine. All subjects were low-risk primigravid women at 37 to 42 weeks' gestation who met our standard criteria for admission to the labor suite (uterine contractions ac-

companied by cervical dilation of 3 cm or ruptured membranes). Additionally, all subjects demonstrated an inadequate pattern defined as a frequency of less than three contractions lasting 40 seconds each in a 10-minute time period.

Eligible patients were required to render informed consent before randomization, which was accomplished by alternating subjects to aggressive management or control groups. Seventy-five patients were assigned to each group in this fashion.

The early aggressive management protocol consisted of amniotomy if required, insertion of a fetal electrode and an intrauterine pressure cannula, and oxytocin infusion. This was accomplished within 30 minutes of the patient's presentation to the labor suite.

Patients in the control group underwent external fetal monitoring. Internal electronic monitoring was reserved for those with nonreassuring fetal heart rate patterns or those patients requiring augmentation. Augmentation was begun in the control group when cervicographic analysis revealed secondary arrest of dilation (no increase in cervical dilation) of >2 hours' duration in the active phase or arrest of descent (no change in station) of 1 hour's duration in the second stage of labor in the presence of an inadequate contraction pattern.

Oxytocin infusion followed a standardized protocol consisting of an initial infusion of 1 mU/min with an increase of 1 mU/min every 30 minutes until an adequate contraction pattern was achieved.

In both groups cesarean delivery for the diagnosis of cephalopelvic dysproportion was performed in the case of arrest of dilation of 3 hours' duration or arrest of descent for 2 hours' duration in the presence of an adequate contraction pattern.

Cesarean delivery because of fetal distress was performed in cases of fetal acidemia or bradycardia that were unresponsive to positional change and cessation of oxytocin infusion if necessary.

Midforceps deliveries were not performed in enrolled patients but low-forceps deliveries were allowed at the physician's discretion.

For cervicographic analysis of labor patterns, the latent phase was defined as the time from presentation until the start of the active phase (the time period during which the rate of cervical dilation was maximal). The deceleration phase was the time period that elapsed between the end of the active phase and complete dilation.

Entries for maternal characteristics, labor progression, and delivery were recorded on data sheets and analyzed by means of the Statistical Analysis Systems statistical analysis package. Differences between groups were assessed by Student's unpaired *t* test and χ^2 analysis with a $p < 0.05$ level considered as significant.

Results

The study and control groups were similar in composition with no significant differences in race or age (Table I). The initial cervical dilation of the study group (2.6 cm) was slightly less than that of the control women (3.0 cm) but there was no difference in either effacement or station.

The groups demonstrated remarkable similarity in the mode of delivery (Table II). The overall rate of cesarean birth was 14%. Eighty-seven percent in the early intervention group (65/75) versus 85% (64/75) of the control group were delivered vaginally. In those patients delivered vaginally, 8% in the early intervention group versus 4% in the control group required forceps. Twenty-eight of 75 patients in the control group ultimately received oxytocin augmentation. Cesarean deliveries were performed because of dystocia in eight patients (10.7%) in the early intervention groups and in nine patients (12.0%) in the control group. The distribution of cesarean sections for arrest of labor in the first or second stage of labor was also similar in both groups (Table II).

Table III. Characteristics of labor*

Table IV. Outcome

	Early intervention group	*Control group*	p *Value**
Birth weight (gm)	3242 ± 57	3224 ± 57	NS
1 min Apgar score	8.33 ± 0.12	7.98 ± 0.15	NS
5 min Apgar score	8.97 ± 0.06	8.95 ± 0.06	NS
Cord pH	7.31 ± 0.01	7.31 ± 0.01	NS

*Student's unpaired *t* test.

The total duration of labor of all subjects in both groups did not differ significantly (7.8 ± 3.7 hours in the study group versus 8.0 ± 3.3 hours in the control group). As expected, subjects delivered by cesarean section because of arrest disorders had considerably longer labors (12.4 ± 4.2 hours) than those delivered vaginally (7.4 ± 3.1 hours) but the duration of labor in these subgroups did not differ between the study and control groups.

Detailed analysis of the cervicographic labor pattern was restricted to those patients achieving vaginal delivery (Table III). The duration of the first and second stages of labor in the two groups did not exhibit a statistical difference. Further analysis showed that the course of labor, when plotted on the standard Friedman labor curve, was comparable. The slope of dilation versus time showed no statistical difference in the latent phase, active phase, and deceleration phase. The number of patients undergoing cesarean deliveries because of dystocia in both groups was small but the characteristics of labor were similar.

Table IV illustrates the comparison of groups by birth weight, Apgar scores, and cord pH. The birth weights were similar as were 1-minute and 5-minute Apgar scores and the values for cord pH. When infants of >4000 gm were isolated, it was found that two of the four in the early intervention group versus both of those in the control group were delivered vaginally.

Comment

The perinatal mortality rate in the United States has fallen markedly over the past 20 years. This drop has coincided with an increasing rate of cesarean birth. A possible cause-and-effect relationship between these trends has been actively debated.[12, 13]

The active management of labor was originally proposed as a means to prevent prolonged labor.[7-10] As the divergence in the rate of operative intervention because of cephalopelvic disproportion between the United States and the British Isles became apparent, some authors attributed this difference to the disparate methods of labor management. O'Driscoll et al.[5, 8, 9] have published a number of reports associating early oxytocin augmentation with a low incidence of cesarean birth for dystocia while maintaining a low perinatal mortality rate.

A recent report comparing the experience at the National Maternity Hospital, Dublin, and the Parkland Memorial Hospital, Dallas, however, cites differences in racial composition and parity as a likely source of the discrepancy in cesarean delivery rate.[6] Nonetheless, preliminary reports have attributed a fall in the rate of cesarean birth as a result of dystocia to the implementation of active management in an American hospital.[14, 15]

In this study we sought to control for differences in the patient population and other, less clearly defined variables by using a prospective, randomized design limited to the subset of most interest, the nulliparous patient in early labor at term with infrequent uterine contractions. Management between groups was identical except for the early implementation of oxytocin infusion and amniotomy.

The study was not designed to replicate the active management protocol outlined by O'Driscoll. Instead, this protocol of early treatment of inadequate uterine

contractions was instituted to determine whether early aggressive treatment would shorten labor and decrease the cesarean section rate when compared with expectant management for variable periods of time. Presently, at our institution as well as many others, patients are treated expectantly for variable periods of time with active intervention being undertaken under different circumstances. We attempted to control for these variables by prospectively randomizing these patients and treating them with strict adherence to the study protocol.

In this environment there was a remarkably similar performance between the two groups. Not only was the incidence of cesarean birth nearly identical, but no significant differences were noted in the length of labor, duration of the phases of labor, or the rate of cervical dilation. These similarities in the progression of labor are important to note as they are likely to be more sensitive to major changes in efficacy then the rate of cesarean birth for dystocia. In a study of this design, assurance of a lack of reduction in the rate of cesarean birth from 12% to 8% (33% reduction) at a probability level (power) of 0.2 would require 900 subjects in each group. The difficulties in a study of this magnitude are obvious. Because of the greater precision in the duration and progression of labor, however, we can exclude, at the same level of certainty, reductions of >33% in the duration of the active phase or >30% in the rate of dilation.

In summary, we have conducted a randomized, prospective trial of early intervention in primigravid women in a large teaching service. In our population early intervention failed to reduce the incidence of cesarean birth as a result of dystocia or to affect the duration of labor. We recommend careful consideration before the widespread use of such methods.

Breast stimulation test and oxytocin challenge test in fetal surveillance: A prospective randomized study

Shlomo Lipitz, M.D., Gad Barkai, M.D., Jaron Rabinovici, M.D., and Shlomo Mashiach, M.D.

Tel Hashomer, Israel

Fifty healthy gravidas with uncomplicated singleton pregnancies at a gestational age of 35 to 42 weeks were assigned at random for the performance of either a breast stimulation test or an oxytocin challenge test after a nonreactive nonstress test. A satisfactory contraction stress test was achieved in 21 of 25 women in the breast stimulation test group and in 24 of 25 women in the oxytocin challenge test group (nonsignificant difference). Significant differences were found in the cumulative rate of achieved contraction stress tests: in the breast stimulation test group 17 of 21 after 20 minutes and 21 of 21 at 50 minutes whereas in the oxytocin challenge test group only four of 24 at 20 minutes, eight of 24 at 50 minutes, and 21 of 24 at 150 minutes. The mean duration for the achievement of a contraction stress test was 20.9 ± 11.5 minutes for the breast stimulation test group and 81.3 ± 48.4 minutes in the oxytocin challenge test group. Uterine hyperstimulation occurred once in each group. No gravida went into labor within 24 hours. Breast stimulation test is a satisfactory alternative to the oxytocin challenge test, is less time-consuming, and is simpler to perform. (Am J Obstet Gynecol 1987;157:1178-81.)

Key words: Fetal monitoring, oxytocin challenge test, breast stimulation test

The contraction stress test and the nonstress test are well-established diagnostic tools for the prenatal evaluation of the fetoplacental unit.[1-3] For practical reasons the nonstress test has been used in most centers as the first diagnostic test followed by a contraction stress test if a nonreactive pattern was obtained.[4, 5] A contraction stress test is usually performed with either spontaneous uterine contractions or after induction of uterine activity by exogenous oxytocin infusion (oxytocin challenge test).[6] Recently several studies have indicated the efficacy of nipple stimulation for the initiation of uterine contractions, suggesting that the breast stimulation test is a convenient method of performing a contraction stress test.[7-10] The breast stimulation test, however, has been associated with a high incidence of uterine hyperstimulation.[11, 12]

The purpose of this study was to compare prospectively the use of intravenously administered oxytocin to nipple stimulation for the induction of uterine activity in the performance of a contraction stress test.

Material and methods

During the study period nonstress tests were performed on every gravida at a gestational age of 35 to 42 weeks either as a routine screening procedure at term or after the perception of decreased fetal movements. Subjects with multiple pregnancies, diabetes, hypertension, intrauterine growth retardation, or a pathologic nonstress test (defined as any type of deceleration) were excluded from this study. Of the 210 subjects fulfilling these criteria, a nonreactive nonstress test was present in 50 patients. A reactive pattern was defined as two fetal heart rate accelerations in any 20-minute period, with each acceleration rising at least 15 bpm above baseline and lasting for at least 15 seconds. The 50 patients with a nonreactive nonstress test underwent contraction stress tests. The participants were randomly divided; 25 underwent an oxytocin challenge test and the other 25 women had a breast stimulation test.

All testing was performed with the patient in the left lateral recumbent position. The procedures included an initial 15-minute recording to determine fetal baseline heart rate and variability. Oxytocin was administered via an infusion pump at a rate of 2 mIU/min. The dosage was raised by 1 mIU/min every 10 minutes until three uterine contractions of at least 40-second duration were recorded during a 10-minute period. At this stage oxytocin administration was discontinued, and fetal heart rate was monitored for an additional 20 minutes.

After the initial 15-minute recording, the women allocated to the nipple stimulation group were instructed to rub the nipple of one breast for 15 minutes. If no adequate uterine activity was recorded, then both nip-

ples were stimulated for another 15 minutes. The fetal heart rate was monitored for 20 minutes after cessation of breast stimulation.

Both the oxytocin challenge test and breast stimulation test were characterized as negative, positive, suspicious (irregular late or variable decelerations), hyperstimulated, and failed. Informed consent was obtained from all women enrolled in the study. All participants were instructed by a nurse before the start of the procedure.

Statistical analysis. Statistical evaluation of the data was accomplished by the unpaired *t* test, the χ^2 test (Yates correction), and the Fisher exact test where applicable. Differences were considered statistically significant with $p < 0.05$.

Results

The mean age of the two study groups was similar (28 ± 5.2 years for the oxytocin challenge test group and 29.7 ± 6.5 years for the breast stimulation test group). The parity of the two groups was similar. The distribution of the participants according to gestational age at the time of the study is shown in Table I. The success rates of the tests in the two groups according to gestational age are depicted in Table II. A satisfactory contraction stress test (three contractions per 10 minutes) was achieved in 21 (84%) gravidas in the breast stimulation test group and in 24 (96%) women in the oxytocin challenge test group. This difference was not statistically significant. All women in both groups acted in accordance with the study protocol, and none of the failures to achieve a contraction stress test could be attributed to inadequate compliance of the participants.

Hyperstimulation of the uterus occurred once in each group. In both subjects at the end of the uterine tetany, the contraction stress test was accomplished without adverse results.

Table I. Distribution of the participants according to gestational age

Gestational age (wk)	*BST group*	*OCT group*
≤37	5	6
38-40	11	14
≥41	9	5
Total	25	25

BST = Breast stimulation test; OCT = oxytocin challenge test.

The time intervals from the initiation of the test until adequate uterine stimulation are depicted in Fig. 1. In 10 (40%) gravidas of the breast stimulation test group, an adequate contraction stress test was obtained during the initial 15-minute period (single-nipple stimulation). Since according to the study protocol the breast stimulation test was planned for a duration of 30 minutes, we compared the number of satisfactory tests achieved during the first 30 minutes with each method. In the oxytocin challenge test group only four women had completed a contraction stress test as desired during this time period compared with 17 subjects in the breast stimulation test group ($p < 0.01$). Four additional patients in the breast stimulation test group achieved a contraction stress test during the 20-minute period after the cessation of nipple stimulation. At that time (50 minutes) only seven subjects in the oxytocin challenge test group had achieved a contraction stress test ($p < 0.01$). The mean time interval from the start of the contraction stress test until the achievement of three contractions within 10 minutes was 20.9 ± 11.5 min-

*Differences between groups not statistically significant.

utes in the breast stimulation test group and 81.3 ± 48.4 minutes in the oxytocin challenge test group.

The clinical outcome of the tests was similar in the two groups (Table III). Uterine activity subsided shortly after the achievement of the contraction stress test, and no gravida went into spontaneous labor within 24 hours after the tests.

Comment

Stimulation of the mammary nipple may lead to uterine contractions during pregnancy, labor, and the postpartum period presumably via activation of the hypothalamus and the oxytocic neurons that end at the posterior pituitary gland.[13] However, studies have failed to detect significant elevations of endogenous oxytocin levels after nipple stimulation.[14] The contraction stress test has been widely accepted as a diagnostic tool for fetal well-being. During a contraction, uterine blood flow is temporarily decreased, which leads to a decline in fetal oxygenation.[8] Although a healthy fetus tolerates these changes, a fetus already compromised by impaired uteroplacental perfusion may not be able to withstand a further decrease in oxygen supply, which will result in pathologic heart rate changes. The contraction stress test has been performed mainly by the intravenous infusion of oxytocin. The exogenous administration of oxytocin requires an intravascular line, accurate monitoring of the administration rate of the potentially hazardous drug, a hospital bed, and a relatively long lag time from the start of administration until adequate uterine stimulation is achieved. The presented results confirm previous studies that concluded that the breast stimulation test overcomes some of these problems.[7,8] The performance of the breast stimulation test was simple and less time-consuming when compared with the oxytocin challenge test whereas the clinical outcome was similar with both methods.

The safety of the breast stimulation test is controversial. Since the endogenous secretion of oxytocin after nipple stimulation leads to persistent uterine contraction during the postpartum period, similar uterine stimulation prenatally may cause uterine hyperstimulation, tetanic contractions, and fetal compromise.[9] We elected to stimulate the nipple manually. Only one nipple was massaged for the first 15 minutes, and the mammae were stimulated subsequently for another 15 minutes or until the occurrence of three uterine contractions within 10 minutes.

In the present study only one patient in each group (4%) had tetanic contractions during the contraction stress test. Similar favorable results with the breast stimulation test have been reported.[7,9,11] However, Hill et al.[12] have documented a high frequency of exaggerated uterine activity.

The high success rate in achieving an adequate contraction stress test in both groups (84% for the breast

stimulation test and 96% for the oxytocin challenge test) is in accordance with previous studies.[7, 8, 12, 15] However, it should be noted that only seven of the women in the oxytocin challenge test group (28%) had an adequate contraction stress test within the first 50 minutes while all successful breast stimulation tests (21 of 25 patients, 84%) were achieved during the same time period ($p < 0.01$). Four of the contraction stress tests in the breast stimulation test group were achieved within 20 minutes of the cessation of nipple stimulation. Previous reports have emphasized the short time needed for the contraction stress test after the breast stimulation test.[7-9, 15]

This randomized study demonstrates that the breast stimulation test is a satisfactory alternative to the oxytocin challenge test. The breast stimulation test was found to achieve clinical results similar to the oxytocin challenge test, was less time-consuming, and was simpler to perform.

Intrapartum use of fetal scalp hematocrit in the diagnosis of profound fetal anemia caused by fetomaternal hemorrhage

Arie Herman, M.D., Yan Bukovsky, M.D., Levi Benson, M.D., Zvi Weinraub, M.D., and Eliyahu Caspi, M.D.

Zerifin, Israel

A case of massive fetomaternal hemorrhage that caused profound fetal anemia is presented. Timely intrapartum assessment of fetal hematocrit of 15% by means of scalp sampling aided in the delivery of a newborn infant with hemoglobin of 3 gm/dl and hematocrit of 10%. (AM J OBSTET GYNECOL 1987;157: 1182-3.)

Key words: Fetomaternal hemorrhage, fetal anemia, scalp hematocrit

Profound fetal anemia is a life-threatening complication and is usually a result of hemorrhage, hemolysis, or isoimmunization. Antepartum and especially intrapartum diagnosis in suspicious cases may be crucial since the fetuses are not able to tolerate the stress of labor. In this case report, timely intrapartum diagnosis of unexpected profound anemia caused by massive fetomaternal hemorrhage helped deliver a healthy newborn infant.

Case report

A 24-year-old, gravida 1, blood type A, Rh-positive patient was referred at 39 weeks' gestation because of decreased fetal movements. Pregnancy was uneventful, and ultrasound examination performed 12 hours earlier was normal except for decreased body movements and absent breathing movements. On admission uterine size was consistent with term, and the cervix was soft, effaced 50%, admitting two fingers, and the head engaged. An oxytocin challenge test after a nonreactive nonstress test was positive (Fig. 1, *A*) and an induction of labor was begun. Amniotic fluid was clear and of a normal amount. Internal monitoring demonstrated a saltatory sinusoidal pattern with decreased variability (Fig. 1, *B*). The results of two scalp pH examinations were 7.29 and 7.28. Because the scalp blood samples

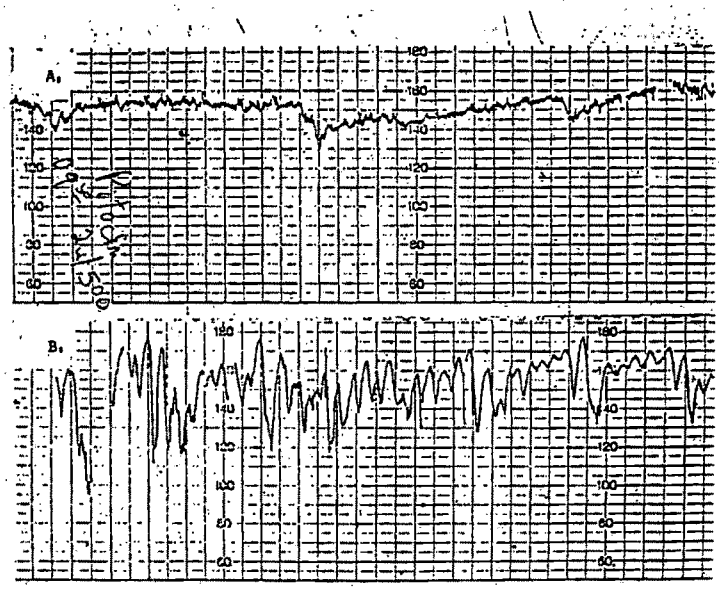

Fig. 1. Fetal heart rate recording. (Uterine contractions are not presented.) **A,** Upper recording. Positive oxytocin challenge test. **B,** Lower recording. Intrapartum internal monitoring.

seemed watery, scalp blood hematocrit level was determined. The result was 15% and an emergency cesarean section was performed. A pale, 3020 gm male infant with an Apgar score of 1 at 1 minute and 5 at 5 minutes, with cord blood pH of 7.25, was delivered. Immediate resuscitation included ventilation and blood transfusion. Initial hemoglobin was 3 gm/dl, hematocrit 10%, reticulocytes 3.8%, and negative hemolytic tests. Neonatal recovery was rapid with spontaneous breathing on the same day with normal astrope. The infant was discharged after 10 days without any abnormal finding.

Developmental examinations during the following year were normal. The peripheral maternal blood test for fetal red blood cells (Kleihauer and Betke) was 2.8% (approximately 150 ml of fetal blood) and established the diagnosis of fetomaternal hemorrhage. Meticulous pathologic examination of the placenta did not show any abnormality.

Comment

Intrapartum diagnosis of severe fetal anemia was described recently by Silva et al.[1] They used scalp hematocrit in a case of vaginal bleeding after amniotomy, and the low hematocrit level confirmed their suspicion of bleeding vasa previa.

Renaer et al.[2] described eight cases and reviewed the entity of fetomaternal hemorrhage as a cause of perinatal mortality and morbidity. In only one case was fetal anemia diagnosed antenatally in an alive fetus. They used maternal blood tests for fetal red blood count and neonatal blood after delivery. Those tests are recommended in any case of trauma, placental abruption, traumatic amniocentesis, external version, or unexplained fetal death.

None of these was valid in our case. In this case the nonpathologic scalp pH almost deceived us. Fortunately, the diluted appearance of the scalp sampling led us to examine fetal hematocrit. The test is feasible in most cases in which scalp sampling for pH is obtainable. We recommend its consideration in any case of suspected fetal bleeding, watery appearance of fetal blood, and significant discrepancy between fetal monitoring and scalp pH.

Prevention of pelvic adhesion formation by different modalities of treatment

Jamil A. Fayez, M.D., and Peter J. Schneider, M.D.
Winston-Salem, North Carolina

This prospective study was designed to investigate the effect of glucocorticoids, promethazine (Phenergan), hyskon, heparin, and Ringer's lactated solution in the prevention of pelvic adhesion formation after pelvic surgery. The patients were divided into two groups: The first consisted of 396 patients who had laparotomy for different types of pelvic surgery, and the second group consisted of 546 patients who had operative laparoscopy for different types of pelvic disease. Patients in these two major groups were divided prospectively into different subgroups with different modalities of adjuvant therapy to prevent postoperative pelvic adhesions. A second-look laparoscopy was performed for some of the patients who failed to conceive in each of these subgroups. Pregnancy rate and adhesion formation were compared between these subgroups with no statistical difference noted. It is concluded that glucocorticoids, promethazine, heparin, and hyskon have no therapeutic advantage over Ringer's lactated solution in the prevention of postoperative pelvic adhesion formation. (Am J Obstet Gynecol 1987;157:1184-8.)

Key words: Adhesion formation, hyskon, promethazine, glucocorticoids, heparin, Ringer's lactated solution

The formation of postoperative pelvic adhesions remains a significant cause of failure in reconstructive surgery for restoration of fertility in women.[1, 2] Avoidance of serosal trauma by gentle tissue handling is thought to be the most important factor in preventing the formation of these pelvic adhesions.[2] Over the years, many drugs and other substances, including glucocorticoids, promethazine, heparin, and dextran, have been used to prevent or reduce the formation of postoperative adhesions.[3-5] Different studies recommended the use of different substances as adjuncts to pelvic surgery to improve the fertility outcome by preventing peritoneal adhesions.[5] Only a few of these studies have attempted to compare the effects of these adjuvants in a strictly controlled clinical manner.[3, 4] The present study was designed to provide a prospective and controlled evaluation of the effectiveness of glucocorticoids, promethazine, hyskon, heparin, and Ringer's lactated solution in the prevention of pelvic adhesion formation in women's infertility surgery.

Material and methods

Two groups of patients were prospectively studied to evaluate the effectiveness of certain drugs and solutions in preventing postoperative adhesions. The first group consisted of 396 women with primary or secondary infertility who had laparotomy for surgical correction of tubal, ovarian, uterine, or peritoneal abnormalities (Table I). One hundred forty of these women (subgroup I) received dexamethasone (Decadron), 20 mg intravenously, and promethazine (Phenergan), 25 mg intramuscularly 4 hours before surgery. The same dose was administered at the beginning of surgery and every 4 hours after surgery for 48 hours. The same dose of dexamethasone and promethazine was instilled into the pelvic cavity along with 200 ml of 32% dextran 70 (hyskon) before closure of the peritoneal cavity. Eighty-six women (subgroup II) received promethazine and hyskon in a manner similar to that used in subgroup I but without dexamethasone. Seventy-four

women (subgroup III) had 200 ml of hyskon instilled into the pelvic cavity before abdominal closure but without any systemic or intraperitoneal medication. In 96 women (subgroup IV) only 400 ml of Ringer's lactated solution was instilled into the pelvic cavity before the parietal peritoneum was closed. The senior author was the main surgeon for all patients in whom microsurgical techniques were used when applicable, with great attention paid to gentle tissue handling. Earlier, patients who had endometriosis, usually of the moderate or severe type, were treated by laparotomy for resection, whereas patients who had no endometriomas were treated by operative laparoscopy regardless of the endometriosis stage. Later when we became more adept with operative laparoscopy, all stages of endometriosis were treated with this procedure. At laparoscopy, endometriosis was scraped or excised and endometriomas were drained and washed.[6,7] Because of the extended nature of this study, patients in the different subgroups who had the same operative procedure were relatively comparable. The study for this laparotomy group took 64 months to complete, with an allocation of 16 months for each subgroup starting with subgroup I and ending with subgroup IV. All patients received 200 mg of doxycycline intravenously at the beginning of surgery and 100 mg intravenously 8 hours after surgery. Doxycycline, 100 mg by mouth, was given twice a day for the first 5 postoperative days. A second-look laparoscopy was done for most of the patients who failed to achieve pregnancy in 9 to 12 months after surgery (Table II).

The second group consisted of 546 women with primary or secondary infertility who had operative laparoscopy for repair of possible pelvic disease (Table III). Patients were divided into three subgroups: The first consisted of 142 women who had 200 ml of hyskon instilled into the pelvis at the conclusion of the operative laparoscopy. The second group consisted of 174 women who had 400 ml of Ringer's lactated solution mixed with 1 gm of hydrocortisone and 2500 U of heparin instilled into the pelvis. The third subgroup consisted of 230 women who had Ringer's lactated solution only instilled into the pelvis at the conclusion of the laparoscopy. The study for this laparoscopy group took 54 months to complete, with 18 months allocated for each of the three subgroups. A second-look laparoscopy was performed for all patients who had severe endometriosis and for most patients who had moderate endometriosis after the completion of their Danazol treatment, which varied from 3 to 6 months. Patients who had undergone other operative laparoscopic procedures but failed to achieve pregnancy in 9 to 12 months received second-look laparoscopy (Table IV). The classification of endometriosis was based on the one adopted and recently revised by the American Fertility Society. It is important to mention that we did not try to assign a subgroup either in the laparotomy or laparoscopy group in whom only strict, meticulous microsurgery would have been performed without any of these adjuvants added because past experience repeatedly taught us that fluid in the peritoneal cavity after surgery is essential for its hydroflotation effect and to inhibit coagulation of the immediately released exudate.

Scoring of adhesions. Description of the sites and extent of uterine, adnexal, and general peritoneal adhesions were made at the time of the first surgical procedure and again at the time of the second-look laparoscopy. The uterus, cul-de-sac, and each tube and ovary were individually scored as 0 for no adhesions, 2 if one third of each of the uterus, tube, or ovary was involved by flimsy adhesions, 4 if two thirds were involved, and 6 if the whole organ was involved. If the adhesions were thick, each of these scores was multiplied by 2. A score of 5 was added if the cul-de-sac was obliterated by flimsy adhesions and 10 if obliterated by thick adhesions.

Results

Table V shows that there was no statistical difference in pregnancy rate between similar procedures for each of the four laparotomy subgroups (χ^2 test, $p > 0.777$). Table II shows the number of patients who had a second-look laparoscopy in each of the four laparotomy subgroups. There was no statistical difference in the rate and quality (median adhesion score) of adhesions developed for each specific procedure in the four subgroups (χ^2 test, $p > 0.733$).

Table VI shows that the pregnancy rate was almost similar for patients who had the same laparoscopic procedure performed, regardless of the subgroup to which they belonged. Table IV shows that no adhesions developed in patients who had pelvilysis, fimbrioplasty, or scraping of mild endometriosis in all three laparoscopic subgroups. No statistical difference was found in the rate or quality of adhesions developed or reformed in the remaining four procedures, regardless of the type of adjuvants used (χ^2 test, $p > 0.806$).

Comment

Movement of the tubes and probably the ovaries is essential for ovum pickup.[8] Because peritubal and periovarian adhesions limit this movement, they are considered a major factor in female infertility.[9] The meticulous reconstructive surgery of the infertility surgeon can be undone by the formation of postoperative adhesions. These adhesions occur after an inflammatory response caused by surgical trauma, anoxia, and foreign bodies such as suture material, bleeding, and infection. The prevention and treatment of pelvic adhesions have been an area of intense interest for infertility surgeons for many years. Intraperitoneal adjuncts and systematically administered drugs, including steroids, antihistamines, dextran, anticoagulants, antiprostaglandins, and antibiotics, were used and studied.[5] None of these agents has been unequivocally successful or unanimously accepted by infertility surgeons, since their effectiveness in preventing postoperative adhe-

sions is still controversial at best. The data in this report show that none of these adjuvants has an advantage over the inexpensive and complication-free Ringer's lactated solution in the prevention of postoperative pelvic adhesions.

An insult to the serosal surface results in the outpouring of fibrinogen, which is changed into a fibrin clot causing the adherence of adjacent structures. This fibrinous attachment then becomes progressively organized into a thick and vascularized fibrous adhesion. In an attempt to prevent the formation of adhesions after laparotomy, we tried four different modalities of treatment using dexamethasone, promethazine, dextran, and Ringer's lactated solution. In theory, dexamethasone stabilizes the cell membrane, decreases histamine release, and antagonizes its effect. In addition, it impedes fibroblast migration and proliferation and collagenous organization. Promethazine decreases histamine release, inhibits the increase in vascular permeability induced by histamine, and protects the cellular lysosome system.[10] The use of intramuscular and intraperitoneal dexamethasone and promethazine to prevent postoperative adhesions was originally described by Replogle et al.[11] These authors and others[12] subsequently promulgated such a systemic and intraperitoneal regimen in abdominal and infertility surgery. This present study and others[13] did not show any significant difference in the frequency or degree of adhesion formation or reformation after surgery between patients receiving dextran, crystalloid solutions, or a combination of dexamethasone and promethazine.

Hyskon, which is a concentrated (32%) high molecular–weight dextran (70,000), became popular subsequent to a report by DiZerega and Hodgen[11] of its apparent efficacy in a controlled study undertaken in four groups of monkeys with surgically induced abrasions. Dextran's mechanism of action remains to be proved. Theories suggest that it has a siliconizing effect and coats raw serosal surfaces and abrasions that prevent fibrinous adhesions. Probably the most important action of intraperitoneal hyskon is its hydroflotation effect that prevents opposition of surfaces. It is slowly absorbed and may stay in the peritoneal cavity as long as 2 weeks, bringing more fluid and thus prolonging its hydroflotation effect.[4] The present study, like previous ones, provides no support for its use because there was no difference in the quality and quantity of adhesion formation between patients treated with hyskon and those treated with Ringer's lactated solution.[3]

Heparin administered systemically or intraperitoneally was reported to be effective in inhibiting adhesion formation or reformation after surgery.[15] Optimal effectiveness was noted when it was administered in relatively high doses and for at least 3 days after surgery. The attendant risk of hemorrhage, as documented in laboratory and clinical studies, forced investigators to abandon heparin use for that purpose until recently.[16] The present study does not show any advantage with the use of intraperitoneal heparin, and therefore we do not recommend its use for the prevention of adhesion formation after surgery. In all laparoscopy subgroups, hyskon, hydrocortisone, and heparin proved to have no advantage over plain Ringer's lactated solution in the prevention of postoperative pelvic adhesion formation.

Over the years, we have kept all tissues exposed in the operative field constantly moist during both microsurgery and macrosurgery. We started with normal saline solution, but this was replaced by Ringer's lactated solution after we noticed that tissues irrigated with normal saline solution for more than 30 minutes blanch and swell and probably sustain minor serosal damage. Continuous irrigation with Ringer's lactated solution prevents fibrin deposition in the peritoneal cavity and washes away fibrinous exudate released from the cut tissue surfaces. The instillation of 400 to 500 ml of Ringer's lactated solution in the cul-de-sac will inhibit coagulation of the released exudate and keep serosal surfaces separated, thereby preventing the formation of fibrinous bridges and later fibrous adhesions. Most female pelvic cavities can accommodate this amount of fluid without any leakage through the incision.

Because infection results in tissue scarring and adhesion formation, almost all infertility surgeons gives some type of known broad-spectrum antibiotics prophylactically. Since antiseptic solutions instilled locally into the pelvis have been found to significantly reduce adhesion formation, there may be some merit to the use of prophylactic antibiotics after reconstructive pelvis surgery.[17] We did not encounter any postoperative pelvic infection probably because we routinely used doxycycline prophylactically. The extended 5-day course of prophylactic antibiotics was not based on scientific data; rather, it was our long-standing routine that never failed, and therefore we became dependent on it.

In summary, this study shows that postoperative adhesion formation can be minimized or even eliminated with gentle tissue handling and if raw surface areas are kept separated for 1 to 2 days after surgery. Plain Ringer's lactated solution seems to do the job, and therefore there is no need for the administration of other agents used in this study. Use of these agents is unnecessary and could prove to be dangerous because of the many side effects they may produce.[5]

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

A thirty-year review of maternal mortality in Oklahoma, 1950 through 1979

Vijayakumar Moses, M.B., B.S., M.D., Sara Reed DePersio, M.D., M.P.H., Dick Lorenz, M.S.P.H., Mark W. Oberle, M.D., M.P.H., Roger Rochat, M.D., and Aurora Fermo, M.D.

Oklahoma City, Oklahoma, and Atlanta, Georgia

Oklahoma's Maternal Mortality Committee has been active since 1941. During the 30-year period 1950 through 1979, the committee reviewed in detail 75.9% of the pregnancy-related deaths that occurred in Oklahoma. The maternal mortality ratio in 1950 was 95.1/100,000 live births, and for 1979 it was 8.1/100,000 live births, a decrease of 91.5%. The risk of death from childbearing remained greater for black women than for American Indian or white women throughout the three decades. For American Indian women, the risk of death associated with pregnancy has decreased and is almost equal to the risk for white women. The Maternal Mortality Committee estimated that two thirds of Oklahoma's maternal deaths were preventable. The proportion of deaths judged preventable did not vary substantially during the study period. We conclude that maternal mortality in Oklahoma can be reduced to fewer than three deaths per 100,000 live births. Intensive monitoring and investigation of deaths and their causes by local maternal mortality committees continues to be an important mechanism for obtaining information to assist health workers in the prevention of deaths. (Am J Obstet Gynecol 1987;157:1189-94.)

Key words: Maternal mortality, Oklahoma, race-specific rates, Native American maternal mortality

The prevention of maternal deaths remains one of the foremost goals of obstetrics, and the maternal mortality ratio has been a widely used measure of the quality of maternal health care. We report here a descriptive epidemiologic study performed on the reported pregnancy-related deaths occurring over 30 years in the State of Oklahoma from 1950 through 1979. This included the analysis of maternal mortality ratios by age, causes of death, and trends over time in three racial groupings—white, black, and American Indian. Preventability factors were also studied.

Material and methods

The Oklahoma Maternal Mortality Committee was organized in 1941[1] by the Oklahoma State Medical Association, in cooperation with the Maternal and Child Health Service (MCHS) of the Oklahoma State Department of Health. Pregnancy-associated deaths were identified by Oklahoma vital statistics from death certificates and sent to MCHS. In order to learn more about the deaths, the committee requested additional information from the physician who had signed the death certificate and from the physician who had treated the mother. All identifying information was removed from the collected information and sent to the committee. After review by the committee, the deaths were classified according to the *Guide for Maternal Death Studies* published by the American Medical Association (AMA) in 1964.[2]

Causes of death have been reclassified by the codes given in the *International Classification of Diseases*, ninth revision, Clinical Modifications (ICD-9-CM), volume 1, 1979.[3] This edition was selected because it has a larger number of pregnancy-related causes of death than previous revisions of the ICD (namely revisions 6, 7, and 8, which were in use during the study period), and the ninth edition is the one in current use. The ICD-9-CM differs from the ICDA-8 and the AMA's classification[2] of maternal deaths in the following respects:

1. ICD-9-CM includes other concurrent conditions in the mothers, such as diabetes and cardiovascular diseases that complicate pregnancy, childbirth, and the puerperium. The AMA defined deaths due to these conditions as indirect obstetric deaths, while ICDA-8 classified them as deaths due to non–pregnancy-related causes.

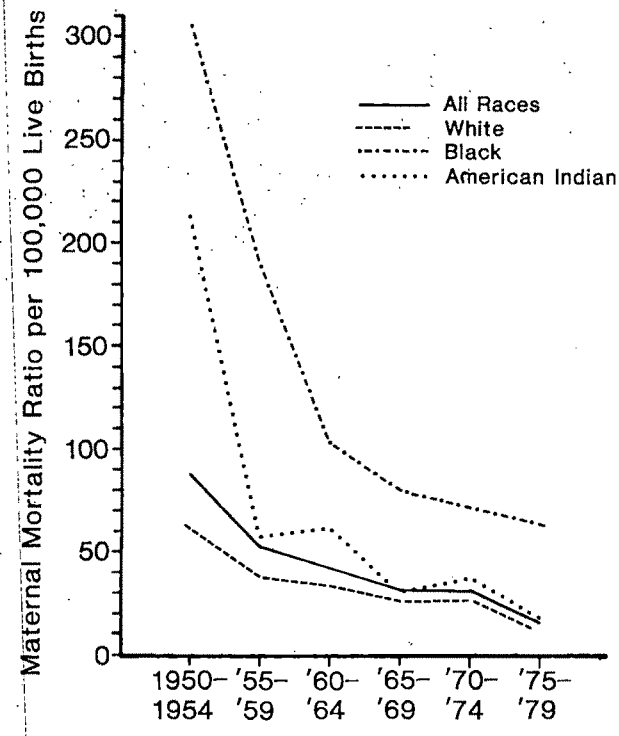

Fig. 1. Maternal mortality ratio by race and by 5-year intervals, Oklahoma, 1950 through 1979.

2. ICD-9-CM includes deaths from maternal infection and parasitic conditions such as venereal diseases and tuberculosis. These conditions are included in the AMA's definition of nonrelated deaths. These conditions are not included in the pregnancy-related causes of deaths in ICDA-8.
3. ICD-9-CM limits maternal deaths to those occurring within 42 days of termination of pregnancy, while ICDA-8 has a time period of up to 1 year after pregnancy termination and the AMA uses a time period of 90 days after pregnancy termination. In ICD-9-CM, deaths that were classified under codes 630-676 were called maternal deaths.

The maternal mortality ratio has been calculated with maternal deaths as the numerator and live births used as the denominator.[4] Thus the maternal mortality ratio is the number of maternal deaths per 100,000 live births. Because Oklahoma's racial groups differ in the distribution of maternal ages, a crude maternal mortality ratio and an age-adjusted maternal mortality ratio was calculated for each racial group, with the aggregate maternal age distribution during 1950 through 1979 as the standard population.[5] The Maternal Mortality Committee, using the *Guide for Maternal Death Studies* published by the AMA,[2] determined whether these maternal deaths could have been prevented. The Maternal Mortality Committee also attempted to establish whether the primary responsibility for these maternal deaths could be attributed to the attending physician, to the patient, or to both.

Results

A total of 632 maternal deaths among Oklahoma residents were reported to the Maternal Mortality Committee during the 30-year period from 1950 through 1979. In addition, the committee received reports of 61 pregnant women who died of causes unrelated to pregnancy, such as malignancies and automobile accidents. These latter deaths were excluded from the analysis. There were 1,405,382 live births in Oklahoma during the 30-year period. Thus the maternal mortality ratio in Oklahoma for 1950 through 1979 was 45.1 per 100,000 live births. The maternal mortality ratio in 1950 was 95.1 per 100,000 live births, and in 1979 it was 8.1 per 100,000 live births. The maternal mortality ratio decreased in the 1950s by 40.4% and in the 1970s by 49.2% (Fig. 1).

The age-specific maternal mortality ratio decreased for each age group during the three decades (Table I). During the 1950s, the age-specific maternal mortality rates were slightly higher for women 15 to 19 years old than those 20 to 24 years old and were highest for older women. The mortality ratio among teenagers declined more dramatically than the ratio for women aged 20 to 24, so that after the 1950s the maternal mortality ratio increased directly with increasing age.

Of the 632 deaths, 64.2% occurred among white women, 27.1% among black women, and 7.2% among American Indian women. Black women had the highest maternal mortality ratio throughout the study period (Fig. 1). The age-adjusted maternal mortality ratio decreased among white and American Indian women during the three decades. Black women showed a more rapid reduction in the mortality ratio between the first two decades, but the age-adjusted maternal mortality ratio for black women actually increased in the 1970s (Table II).

To compare maternal mortality ratios in the three racial groups, we divided two race-specific maternal mortality ratios to obtain a ratio of ratios or a "risk ratio." Thus for pregnant black women the risk of pregnancy-related death was 4.6 times greater than the risk for white women during the first decade of the study; this ratio decreased in the 1960s (2.7) but increased in the last decade (4.8). On the other hand, American Indian women's risk of pregnancy-related death was 3.2 times greater than the risk for white women during the 1950s, but this risk ratio steadily declined to 1.2 in the 1970s (Table II).

The proportion of maternal deaths attributed to hemorrhage, preeclampsia-eclampsia, and abortion complications (which were the three leading causes of maternal mortality) declined from 1950 through 1979,

Table I. Number of maternal deaths and maternal mortality ratio per 100,000 live births by age and decade, Oklahoma, 1950 through 1979

Age group (yr)	Total (1950-1979)		1950-1959		1960-1969		1970-1979	
	Ratio	No. of deaths	Ratio	No. of deaths	Ratio	No. of deaths	Ratio	No. of deaths
15-19	26.6	75	46.7	41	19.0	19*	15.3	15
20-24	25.6	135	34.2	61	22.7	40	19.7	34
25-29	46.2	156	70.8	87	39.6	40	25.5	29
30-34	71.2	114	105.9	74	56.7	28	29.5	12
35-39	133.5	96	166.1	58	114.0	28	80.6	10
≥40	253.4	55	334.2	36	206.9	16	95.5	3
Total	45.1	631	65.2	357	37.7	171	25.6	103

*Includes one 14-year-old girl in 1967.

Table II. Age-adjusted maternal mortality ratio per 100,000 live births by race, decade, and risk ratio, Oklahoma, 1950 to 1979

	Total (1950-1979)		1950-1959		1960-1969		1970-1979	
	Ratio	No. of deaths	Ratio	No. of deaths	Ratio	No. of deaths	Ratio	No. of deaths
Race								
All races	45.1	632	65.2	357	37.7	172	25.6	103
White	34.1	406	46.4	220	31.0	138	19.3	68
Black	129.5	171	214.3	102	83.2	40	92.6	29
Indian	67.4	55	144.3	15	53.7	54	22.7	6
Risk ratio								
Black/white	3.8		4.6		2.7		4.8	
Indian/white	2.0		3.2		1.7		1.2	

while the proportion of deaths due to puerperal infections and ectopic pregnancy increased (Table III).

Of the 632 maternal deaths, the marital status of 590 women was known (93.3%). Among deaths of women with known marital status, a total of 86.4% of maternal deaths occurred among married women. In the 1950s 89% of maternal deaths occurred among married women, while in the 1970s this percentage declined to 80.4%. Data on births by marital status were not available to calculate a maternal mortality ratio by mother's marital status.

Throughout the period, autopsies were performed in 203 maternal deaths in Oklahoma. The proportion of deaths with autopsies reported increased from 11.3% in 1950 to 1954 to 57.1% in 1975 to 1979. Similar increases occurred among all racial groups.

Although the total number of deaths among women of reproductive age decreased by 14% between 1950 to 1954 and 1975 to 1979, the proportion of maternal deaths decreased even more. Thus in 1950 to 1954 maternal deaths represented 6.5% of all deaths among women aged 15 to 44 while in 1975 to 1979 maternal deaths represented only 1.2%, a relative decrease of 81.5% (data not shown). This decrease occurred throughout the period among white and American Indian women; however, among black women, a slight increase occurred in the last 5 years of the study.

The Oklahoma Maternal Mortality Committee assessed preventability and responsibility factors in 75.0% of the maternal deaths. Throughout the study period, preventable factors were identified for 66.9% of those evaluated. The number of maternal deaths that had preventable factors identified decreased from 105 in 1950 to 1954 to 25 in 1974 to 1979, a relative decrease of 76.2% (Table IV), while the total number of maternal deaths decreased from 224 in 1950 to 1954 to 36 in 1974 to 1979, a relative decrease of 83.9%. The committee attempted to establish whether the primary responsibility for these maternal deaths was attributable to physician, patient, or both. They found that physicians were responsible for factors that could have been prevented in 52.1% of the assessed maternal deaths. Patients were responsible for factors that could have been prevented in 33.8% of the assessed deaths, and the physicians and patients combined were responsible for preventable factors in 11.7% of the maternal deaths. The percentage of maternal deaths with preventable factors that were the responsibility of the physician increased from 41.9% in 1950 to 72.2% in 1965, then declined to 40% in 1975 to 1979. In the same period,

Table III. Causes of maternal deaths by decade and race, Oklahoma, 1950 through 1979 (percentage distribution)

Cause	Total (1950-1979)	All races			Race-specific (1950-1979)		
		1950-1959	1960-1969	1970-1979	White	Black	Indian
Hemorrhage	24.4	27.2	22.1	18.5	24.9	21.0	30.9
Preeclampsia-eclampsia	17.1	20.5	12.8	12.6	15.3	19.9	21.8
Complications of abortion	8.7	8.7	9.3	7.8	8.1	9.4	10.9
Puerperal infection	7.2	3.5	9.9	15.5	7.4	4.1	16.4
Ectopic pregnancy	7.0	6.2	5.8	11.7	5.2	12.9	1.8
Amniotic fluid embolism	4.3	1.7	8.7	5.8	5.2	2.3	3.6
Pulmonary embolism	4.3	4.2	5.8	1.9	5.7	1.8	1.8
Complications of anesthesia	5.2	4.8	6.4	4.9	4.4	8.2	1.8
Cardiovascular disorder	7.0	8.7	5.2	3.9	7.6	6.4	3.6
Others	14.8	14.5	14.0	17.4	16.2	14.0	7.4
Total	100.0	100.0	100.0	100.0	100.0	100.0	100.0
No. of deaths	632	357	172	103	406	171	55

Table IV. Responsibility for preventable factors resulting in maternal deaths assessed by Maternal Mortality Committee, Oklahoma, 1950 through 1979 (percentage distribution)

Responsibility	Years					
	1950-1954	1955-1959	1960-1964	1965-1969	1970-1974	1975-1979
Physician	41.9	50.4	59.6	72.2	61.5	40.0
Patient	40.0	34.0	25.4	16.7	28.2	56.0
Physician and patient	15.2	2.4	12.8	11.1	5.2	4.0
Other	2.9	3.2	2.2	0.0	5.1	0.0
Total	100.0	100.0	100.0	100.0	100.0	100.0
Estimated No. of preventable deaths	105	65	47	36	39	25

the percentage of maternal deaths with preventable factors that were the responsibility of the patient decreased gradually from 40.0% in 1954 to 16.7% in 1965 to 1966, then climbed up to 56.0% in 1975 to 1979.

Comment

The decline of maternal mortality in Oklahoma closely parallels that of the United States as a whole. Oklahoma's maternal mortality ratio, as calculated by the National Center for Health Statistics, was 85.2/100,000 live births in 1950 and 10.1/100,000 live births in 1979, a decrease of 88.2%. During the same period, U.S. maternal mortality ratios decreased by 90.6%.

Studies in several states found that the incidence of maternal mortality was higher than that reported through the standard vital records reporting systems.[6-9] The method of ascertaining maternal deaths through maternal mortality committee review may be more complete than using national vital statistics alone.[8] The rates observed in this study are higher than those obtained from the National Center for Health Statistics. These studies have underscored the importance of improved surveillance in identifying maternal deaths. The maternal mortality committee is one way of clarifying the cause of maternal deaths.

Many reported studies calculated the maternal mortality ratio with direct obstetric death as defined by the guidelines set by the AMA used as the numerator.[9, 10] Rochat[12] emphasized that if pregnancy-related deaths were to be used as the numerator instead of direct obstetric deaths, the ratio may be twice as high as the current reported maternal mortality ratio. ICD-9-CM comes closer to measuring pregnancy-related deaths than the AMA classification or previous revisions of the ICD. For the 30-year period of this study, use of the ICD-9-CM classification resulted in 23.8% more deaths classified as maternal deaths when compared with those classified by the AMA's direct obstetric death classification.

Smith et al.[13] classified all maternal deaths in the United States from 1974 to 1978 by using ICD-9-CM and ICDA-8 and found that the use of ICD-9-CM resulted in an increase of 8.8% over ICDA-8 in the number of deaths classified as maternal deaths. All maternal deaths identified in this study occurred less than 42

days after delivery and met the ICD-9-CM definition of maternal death.

The race-specific analysis revealed that among black and American Indian women, maternal mortality ratios are still higher than the ratio for white women. The risk of death from childbearing remained greater for black women, while for American Indian women, the risk of death due to pregnancy has decreased and is similar to that of white women. The improvement in the American Indian maternal mortality ratio in Oklahoma may reflect improvements in obstetric care, improvements in socio-economic status, or an artifactual difference in reporting racial status on birth or death certificates. The important observation from the perspective of health care services is that the difference between ratios for black women and those for white women did not decrease. In fact, this difference has increased in the last decade. This difference is due in part to the increased proportion of maternal deaths of black women that are due to ectopic pregnancy and preeclampsia-eclampsia.

The percentage of deaths due to maternal causes among black women of reproductive age was higher than the percentage of deaths due to maternal causes among American Indian and white women. Factors contributing to this elevated risk are that black teenagers have a higher fertility rate than white teenagers in Oklahoma[14] and that black women may wait until later in their pregnancies than American Indian or white women to seek prenatal and obstetric care.

The study of Buehler et al.[15] revealed that black women aged 35 or older are at significantly higher risk of death than white women and their risk was even greater for deaths associated with abortive outcomes (including ectopic pregnancy). A significant finding was the higher rate of deaths in ectopic pregnancy among older black women. This reflects the fourfold higher rate of ectopic pregnancies among black women aged 35 and older compared with white women in the United States. One contributing factor to death from ectopic pregnancy is a failure to diagnose early pregnancy among women aged 35 and older. The diagnosis of ectopic pregnancy by physical examination is more difficult in these women because a greater proportion are overweight.[16]

Progress has been made in reducing the number of maternal deaths in Oklahoma, especially those due to hemorrhage, preeclampsia-eclampsia, and complications of abortion. In 1965, Crosby[17] reported that hemorrhage was the leading cause of maternal deaths, and a later study by Jimerson and Crosby[18] showed that hemorrhage continued to be the leading cause of maternal death in Oklahoma. More recently, hemorrhage has dropped behind preeclampsia-eclampsia as the leading cause of maternal deaths.[19]

The number of maternal deaths due to preeclampsia-eclampsia fell precipitately between the 1950s and the 1960s. Tyler and Saeger[20] reported that preeclampsia-eclampsia was the leading cause of pregnancy-related deaths among American Indian women in eastern Oklahoma in 1965. Vaughn[21] reported that 30% of total maternal deaths among American Indians in New Mexico were due to preeclampsia-eclampsia. Our study also showed a similar pattern among American Indians in Oklahoma. Pregnant American Indian women are two and a half times more likely to die of preeclampsia-eclampsia than are white women. Early identification of high-risk women may well prevent maternal mortality caused by preeclampsia-eclampsia.[20]

Although complications of abortion were the third leading cause of maternal deaths in Oklahoma over the entire period, there were no deaths due to complications of induced abortion during the last 5 years. This may be due to widespread use of effective methods of contraception and to the availability of safe, legal abortion in Oklahoma.

Among all maternal deaths, the percentage of women who were single has more than doubled in the 30-year period; this phenomenon is particularly notable among black women. These deaths may reflect the trend of more births occurring out of wedlock in recent years and the higher percentage of out-of-wedlock births among black teenage women than among American Indian or white women.[14]

Since preventable factors were identified in two thirds of the maternal deaths evaluated, maternal mortality in Oklahoma could be reduced to three deaths per 100,000 live births. However, achieving this residual reduction in mortality will require intensive efforts to understand the events leading to maternal death.

Clinical data are particularly useful in determining the evaluation of events that led to the woman's death, but clinical data alone do not always provide adequate information to accurately classify the cause of death. Autopsies provide useful additional information. Although the proportion of maternal deaths evaluated with autopsies increased over the three decades studied, clinicians should continue to strive to obtain permission for autopsies to determine the specific pathologic causes of maternal death.

Although the recent dramatic decrease in Oklahoma's maternal mortality is encouraging, continued effort in mortality surveillance and health education will be necessary to meet these objectives.

Anorexia nervosa, bulimia, and pregnancy

Donna E. Stewart, M.D., Joel Raskin, M.D., Paul E. Garfinkel, M.D., Ophelia L. MacDonald, M.D., and G. Erlick Robinson, M.D.

Toronto, Ontario, Canada

Of 74 women previously treated for anorexia nervosa or bulimia, 15 had conceived 23 pregnancies when assessed at follow-up. The status of the eating disorder, course of pregnancy and delivery, infant health, and postpartum adjustment are described. Women in whom eating disorders were in remission at conception had greater maternal weight gain and babies with higher birth weights and 5-minute Apgar scores than women who conceived while they still had symptoms of restricting anorexia nervosa or bulimia. Women who had symptoms of eating disorders at conception also had continuance or worsening of these symptoms during pregnancy and the postpartum year. We recommend delay of pregnancy until the eating disorder is truly in remission. (Am J Obstet Gynecol 1987;157:1194-8.)

Key words: Anorexia nervosa, bulimia, pregnancy, infants

The high prevalence of anorexia nervosa and bulimia among young women,[1] combined with more effective treatment of these conditions, has resulted in more of these women eventually becoming pregnant. Little is known about the course of pregnancy in these women and even less is known about the health of their infants. Many psychological conflicts thought to be important in patients with eating disorders concerning adult sexuality, body image, autonomy, dependency, and relationships to parents are highlighted during normal pregnancy. This has led to speculation that pregnancy

is especially stressful for women with eating disorders and that psychiatric difficulties, including exacerbation of anorexia nervosa and bulimia, are likely to occur during their pregnancy or postpartum period.

In reviewing the literature of the last 30 years, we found nine multiple case reports of three to 86 pregnancies occurring in women who had previously or concurrently suffered from anorexia nervosa.[2-10] Of these, only the study of Hart et al.[8] gave the periods of gestation and infant birth weights, and none gave the Apgar ratings of the infants. By far the largest study in this group by Brinch et al.,[10] published in Danish in 1985, reported 86 pregnancies occurring in 50 women who had been treated for anorexia nervosa during the previous 4 to 22 years. This study surprisingly reported seven perinatal deaths, with six attributed to prematurity. Unfortunately, weight gain in pregnancy, the length of gestation, infant weights, and Apgar scores were not reported for the study group. Seven single case reports published during the same period of time suffered from similar omissions. In the majority of these studies, many important factors, such as the status of the eating disorder, maternal weight gain, gestational period, psychological complications during and after pregnancy, infant birth weight, and Apgar ratings, were unreported.

It is the purpose of this study to report on the course of pregnancy and the health of the infants in a North American group of women treated for eating disorders, to determine the effects, if any, of anorexia nervosa and bulimia on their pregnancies, infants, and postpartum adjustment.

Material and methods

Seventy-four women treated for anorexia nervosa of the restricting or bulimic forms (according to the criteria of Garfinkel and Garner[11]) at a University of Toronto Eating Disorders Clinic between 1970 and 1978 were interviewed as part of a study of their long-term outcome.[12] Approval was obtained from the University of Toronto Review Committee on the Use of Human Subjects for the women to be contacted and interviewed and their charts reviewed to determine the course of any pregnancies that occurred after the diagnosis of the eating disorder. Of these women, 15 were identified as conceiving a total of 23 pregnancies. A variety of factors were identified in the 59 women who had not been pregnant; single status, infrequent intercourse, contraceptive use, and failure to conceive.

Information on those women who had had pregnancies after treatment for anorexia nervosa with or without bulimia was obtained from patient interviews and charts about four topic areas: the eating disorder, the course of pregnancy and delivery, the health of the infant, and the maternal complications including postpartum adjustment. These data are presented in Table I and are complete except for 5-minute Apgar scores for three healthy term babies with an average weight of 2722 gm, delivered vaginally of one mother in England.

The women were divided into three groups dependent on the status of the eating disorder at conception: patients with restricting anorexia nervosa who did not experience bulimia and who controlled weight primarily by caloric restriction; patients with bulimic anorexia who engaged in binge eating usually followed by self-induced vomiting or purging, and patients in remission without symptoms of eating disorder at conception.

The average age at first diagnosis of the eating disorder was 20 years for the women with restricting anorexia nervosa; 21 years for the bulimic women, and 18 years for the women in remission, with a range from 14 to 23 years. Eleven patients had been hospitalized from one to four times because of their eating disorder. The women with restricting anorexia and bulimic anorexia had been admitted an average of once per patient and the women in remission had been admitted an average of 1.5 times per patient.

Eight women who were asymptomatic at conception and in remission had 13 pregnancies; four women had active restricting anorexia and had seven pregnancies, and three women were binging, vomiting, and purging and had three pregnancies.

For purposes of statistical analysis all relevant information for these three groups was compared by use of one-way analysis of variance followed by Duncan's multiple range test for each of maternal weight gain, birth weight, and 5-minute Apgar scores.

Results

Pregnancy and delivery. All the women were married at the time of conception. The average age at conception was 27 years for those with bulimic anorexia and those in remission and 25 years for those with restricting anorexia. The average length of time from the initial diagnosis of eating disorder until conception was 9 years for the women in remission, 6 years for the bulimic group, and 5 years for the women with restricting anorexia. Weight gain in pregnancy varied from a loss of 8 pounds in a woman with restricting anorexia, S(12), who subsequently had a spontaneous abortion at 12 weeks, to a gain of 60 pounds in a previously bulimic woman, S(3), in remission. From Table II, it can be seen that those women in remission gained significantly more weight than those women with restricting anorexia nervosa and that the women with active bulimia gained even less ($p < 0.005$).

Of the 23 pregnancies conceived by the 15 women, 20 of them proceeded to live births; S(9) had an intrauterine death at 15 weeks, S(12) had a spontaneous abortion at 12 weeks, and S(7) underwent an elective abortion at 10 weeks.

Table II. Results of one-way analysis of variance in three groups of patients

	Remission (mean ± SD)	*Restricting anorexia*	*Bulimia*	*f Ratio*	*Level of statistical significance*
Maternal weight gain (lbs)*	28.0 ± 11.9	15.8 ± 3.3	5.7 ± 6.7	7.14	$p < 0.005$
Infant birth weight (gm)*	3592.0 ± 518.8	2744.4 ± 414.3	2362.7 ± 236.2	11.27	$p < 0.008$
Apgar score (5 min)†	8.8 ± 1.1	7.5 ± 2.1	4.0 ± 1	18.32	$p < 0.001$

*Significantly greater in remission group than in other groups (Duncan's test, $p < 0.05$).
†Significantly less in bulimic group than in other groups (Duncan's test, $p < 0.05$).

Of the 13 pregnancies that occurred in women in remission, only one had recurrence of eating disorder symptoms during pregnancy. The one patient, S(1), who encountered problems was a previously bulimic woman in remission, who started restricting food during her first pregnancy but was in remission throughout her second pregnancy 4 years later. In contrast, most patients who had symptoms of the eating disorder at conception reported worsening symptoms or psychological difficulty during pregnancy. Hospitalization for eating disorders during pregnancy occurred in two women, S(12), the woman with restricting anorexia who spontaneously aborted at 12 weeks, and S(14), who had bulimia. Both of these women had eating disorder symptoms at conception that seriously worsened during pregnancy.

In 18 of the 20 live births, the infants were delivered vaginally at 36 to 40 weeks' gestation. The average duration of gestation for term pregnancies was 37 weeks for the women with bulimia, 38 weeks for the women with restricting anorexia, and 39 weeks for women in remission. There were two cesarean sections, both in women with active bulimia: S(15), who had gained 4 pounds by 38 weeks, and S(14), who had not gained any weight by 36 weeks' gestation. In summary, all the complications of pregnancy and delivery occurred in women who were ill at conception.

Health of infants. The birth weights of the infants were significantly different among the three groups of women ($p < 0.008$). Women in remission had heavier babies in comparison with those of the women with restricting anorexia and bulimia (Table II). Infants of mothers in remission also had higher 5-minute Apgar scores when compared with mothers with restricting

and bulimic forms of anorexia nervosa ($p < 0.001$) (Table II). As noted earlier, the two fetal deaths (a spontaneous abortion and an intrauterine death) occurred in women who were ill at conception. Only two infants were reported to have had difficulties after birth and both were born to bulimic mothers. The infant of S(13) weighed 2552 gm after spontaneous vaginal delivery at 37 weeks. The mother had gained 13 pounds during pregnancy. The infant had respiratory distress with a 5-minute Apgar score of 4. The infant of S(14) weighed 2098 gm, was jaundiced, and had a 5-minute Apgar score of 3. A cesarean section was performed at 36 weeks, and there had been no weight gained during pregnancy.

Postpartum adaptation. Six of the eight patients in remission at conception remained well for 1 year post partum. Of the two who had difficulty, S(2) developed a recurrence of anorexia nervosa shortly after her first delivery and has since developed an anxiety disorder after her third child. S(3) developed a major affective disorder 4 months post partum. In contrast, all seven women who were ill at conception continued to be ill or had worsening of the eating disorder in the postpartum year.

Of the 10 infants who were successfully breast-fed for 6 months or longer, nine were born to women in remission, one to a bulimic woman S(13), and none to women with restricting anorexia.

Comment

Despite the small numbers of women in the sample groups, some patterns emerged that have treatment implications. If the eating disorder is in remission, then an uncomplicated pregnancy and healthy baby can probably be expected. Our data for these women in remission do not support the Danish study by Brinch et al.[10] reporting high perinatal mortality rates in their infants, but further investigations are required. Especially important is the definition of remission of the eating disorder. In a related publication[12] we have shown that women who have had an eating disorder and are thought to be recovered have no more features of continued illness than a control group of women of comparable age. Women with active anorexia nervosa and bulimia at the time of conception had many difficulties, as shown in Table II; they gained less weight in pregnancy and had smaller babies with lower 5-minute Apgar scores. They also had frequent worsening of the eating disorder symptoms during pregnancy and the postpartum period, a finding similar to that recently reported by other investigators.[13] They also appear to have more difficulty with breast-feeding.

Some of these findings can be explained on the basis of the low weights of the actively ill women at the time of conception. A recent American study shows that pregravid body mass and pregnancy weight gain both significantly influence birth weight.[14] Literature from the Third World and Dutch famine suggest that the woman's weight-for-height before conception is as valid a predictor of maternal weight gain and infant weight as is nutritional status during pregnancy.[15] If this is so, then women with restricting anorexia and bulimia are at extra risk because they are underweight when they become pregnant and do not usually achieve adequate nutrition during pregnancy. It must be emphasized that some bulimic women may appear to be at a normal weight if one consults normative charts, but since they have been significantly overweight before becoming ill they may be undernourished relative to what is normal for them.[16]

At present it seems prudent to advise anorexic and bulimic women who wish to become pregnant to wait until the eating disorder is truly in remission, because the pregnancies and infants of such women may be at higher risk. We have similarly reported[17] that some women with eating disorders causing amenorrhea, who presented to an infertility clinic seeking hormonal induction of ovulation, had pregnancies complicated by the eating disorder and produced smaller babies with depressed Apgar scores. It would therefore seem wise for obstetricians to inquire about a history of eating disorder in infertile women and to counsel delay of pregnancy until the anorexic or bulimic symptoms have stopped. It would seem most helpful for the physician

to ensure that appropriate psychiatric treatment and follow-up are in place for the eating disorder rather than attempt to induce ovulation.

Physicians should also consider the possibility of an eating disorder in women who fail to gain appropriate weight during pregnancy or who present with intractable vomiting or purging. We recognize the need for further prospective studies with larger groups of women, looking at the course of the eating disorder during pregnancy and follow-up of their children.

We gratefully acknowledge the statistical assistance of Marion Olmstead.

Effects of aerobic and strength conditioning on pregnancy outcomes

Douglas C. Hall, M.D., and David A. Kaufmann, Ph.D.
Ocala and Gainesville, Florida

This study evaluated the effects of a physical conditioning program on pregnancy outcomes and the subjective pregnancy experience. Pregnancy outcomes included length of labor, mode of delivery, length of hospitalization, and gestational age, birth weight, and Apgar scores of newborn infants. Subjective data included level of tension, general physical comfort, and self-image. The 845 subjects in the study were divided into a control group (n = 393) and into groups of low, medium, and high levels of exercise (n = 82, 309, and 61, respectively). Exercise sessions consisted of treadmill or bicycle warm-up, individually prescribed exercises on weight-lifting equipment for arms, legs, abdomen, and back, and 1- to 2-mile workout on bicycle ergometer. Pregnancy outcomes were more favorable in the exercise groups, particularly the high-exercise group. Significant data included length of hospitalization, incidence of cesarean section, and Apgar scores. All patients reported positive subjective responses to the conditioning program. (AM J OBSTET GYNECOL 1987;157:1199-203.)

Key words: Exercise during pregnancy; physical conditioning in pregnancy; strength conditioning in pregnancy; weight training in pregnancy; aerobic conditioning in pregnancy

An estimated 15 to 20 million women in the United States are actively involved in organized exercise programs.[1] Millions of others exercise on their own. Of these, an unknown number are pregnant or plan a pregnancy.

Pregnant women need a safe, efficient, and productive means of improving or maintaining muscular and cardiovascular strength and endurance throughout gestation. Their bodies may then meet the progressive physical demands of pregnancy in a more comfortable manner. Particularly, prescribed exercise enables their bodies to compensate for the anterior shift in the center of gravity as term approaches. Without compensation, this shift produces biomechanical changes that frequently cause physical discomfort and necessitate curtailment of activities.

Studies in the literature increasingly deal with the effects of aerobic exercise during pregnancy.[2-6] However, the cardiovascular component is only one of the enabling or limiting factors affecting prenatal, natal, and postpartum function. Equally important is the neuromuscular component, which has been virtually ignored in pregnancy for many reasons. To fill this unmet need, we designed the exercise protocol described in this report.

From the Department of Exercise and Sports Sciences, University of Florida.

The purpose of this study was to determine the effects of physical conditioning on both quantifiable pregnancy outcomes and the subjective experience of pregnancy. It was our hypothesis that the development of the muscular strength and/or flexibility needed to support the enlarging organs of the pregnant woman and improvement of her aerobic fitness have two main effects: (1) minimization of biomechanical changes during pregnancy and therefore lessening of prenatal discomfort and (2) minimization of labor and delivery complications. Prenatal comfort was assessed by subjective reports of the patient and included tension level, general physical comfort, and sense of well-being. Labor and delivery data included length of labor, type of delivery, length of hospital stay, and gestational age, birth weight, and 1- and 5-minute Apgar scores of the neonate. In addition, postnatal evaluation of the patient's labor and delivery experience and postpartum recovery was conducted.

Material and methods

Subjects. The subjects in the study consisted of 845 pregnant women who received obstetric care in private practice settings in Ocala, Florida. Subjects were referred to the exercise program by seven board-certified obstetricians. The women in the study were middle to upper middle class in socioeconomic status. Age and parity of the women appear in Table I.

Preliminary evaluation. An initial history was recorded and physical examination performed by each subject's obstetrician in the private practice setting. If no contraindications to exercise were identified, the

5 min Apgar score	9.3	9.1	9.5	9.6
Hospitalization (days)	2.9	2.6	2.5	2.2

subject was given the option to participate in an exercise program designed specifically for pregnant women. The exercise center at which this program was offered (Pregnagym) was located in a special facility adjacent to the offices of D.C.H.

At the exercise center, a detailed fitness evaluation was carried out by a physician specializing in exercise physiology. The evaluation included: (1) resting heart rate, (2) resting blood pressure, (3) standard physical therapy postural examination to identify lengthened and/or shortened muscle groups, (4) summation of skin-fold thickness in the triceps, subscapular, and suprailiac areas with a Lange skin-fold caliper, and (5) test of predicted submaximal oxygen uptake on a bicycle ergometer. In addition, a history was taken of past or present orthopedic, obstetric, or cardiopulmonary problems. The muscular and cardiopulmonary demands of the patient's vocational and recreational activities were also assessed. (This evaluation was repeated at 10-week intervals throughout the pregnancy.)

Exercise prescription. Historical findings and the results of all tests were used in determining the subject's exercise prescription. Exercise prescriptions had three components: (1) treadmill or bicycle warm-up, (2) use of selected exercise machines, and (3) aerobic workout on exercise bicycles.

The warm-up consisted of 5 minutes on a treadmill at a walk/jog rate of 3 to 4 mph or 5 minutes on an exercise bicycle at 300 kilopond meters (kpm).

After the warm-up period, the subject was assigned to workouts on exercise machines selected to strengthen and/or increase the flexibility of desired muscle groups of the upper and lower extremities and trunk on the basis of her evaluations. The amount of resistance on each machine was individually determined. If evaluation had revealed shortened muscle groups, the prescription was designed to lengthen these muscles by stressing the flexibility portion of the exercise without increased resistance. Progressive resistance was used for muscle groups that were found to be lengthened and needed strengthening. Once the subject was able to complete 12 repetitions in good form the resistance was adjusted on the basis of her individual capabilities. Total exercise duration averaged 45 minutes.

The final component of the prescription was an aerobic workout on one of various exercise bicycles. A resistance of approximately 300 kpm for 1 to 2 miles was prescribed for most women. Resistance was prescribed to accelerate heart rate to 85% of maximum (not to exceed 140 bpm).

Subjects were asked to exercise 3 days per week and were encouraged to continue training until the onset of labor or until a medical contraindication developed (this did not occur in any of the subjects). Individual training sessions were conducted by three full-time exercise instructors with special training in obstetric physiology and conditioning as well as the psychological aspects of pregnancy. Records of each exercise session were maintained.

Because of the progressive nature of the physical changes of pregnancy, repeat evaluations were scheduled every 10 weeks, and the subject's exercise prescription was modified accordingly. In addition, continuous maternal and fetal heart monitoring was performed, with a Litton 660 fetal monitor, throughout one session in the twenty-eighth week of gestation and another in the thirty-eighth week.

Study groups. Subjects were categorized into four groups, depending on the number of exercise sessions completed during the pregnancy. Control subjects (n = 393) had a mean of 0.8 sessions (range 0 to 10). The low-exercise group (n = 82) had a mean of 15 sessions (range 11 to 20). The medium-exercise group (n = 309) had a mean of 32 sessions (range 21 to 59). The high-exercise group (n = 61) had a mean of 64 sessions (range 60 to 99).

Data collection. The data were collected retrospectively from the hospital and exercise center records of the patients. Medical data included total labor time,

duration of the second stage of labor, incidence of cesarean section, length of hospital stay, gestational age of the neonate, birth weight, and 1- and 5-minute Apgar scores. At 6 weeks post partum, all participants were surveyed regarding their subjective responses to the exercise program: (1) self-image, (2) reduction in discomforts of pregnancy (for example, low back pain), (3) relief of tension, and (4) in multiparous patients, the rapidity of the recovery period compared with that of previous pregnancies.

Statistical treatment of the data regarding pregnancy outcome was done by simple analysis of variance and, when necessary, Duncan's multiple range test. A p level of 0.05 was selected to denote statistical significance.

Results

Mean lengths of labor in the study groups were calculated only for primigravid women, since multigravid women have shorter total labors and second stages of labor and there was a discrepancy in the representation of multigravid women among the groups. No significant differences in times of labor were found.

The rate of cesarean section was only 6.7% in the high-exercise group and 19.0% in the medium-exercise group, compared with 28.1% in control subjects and 23.1% in the low-exercise group ($p < 0.0001$) (Table I).

Birth weights of babies of control mothers averaged 65 to 151 gm below those of mothers in the three exercise groups (Table I), with the greatest contrast (151 gm) occurring between the control and high-exercise group ($p = 0.06$).

Babies of high-exercise mothers had slightly higher 1-minute Apgar scores (mean 8.9) than babies of mothers in the control group (8.6), low-exercise group (8.8), and medium-exercise group (8.7) ($p < 0.05$). The mean 5-minute Apgar scores for babies of mothers in the high-exercise group were also slightly higher than those for babies of mothers in the control and medium-exercise groups, that is, 9.6 versus 9.3 and 9.1 ($p < 0.05$) (Table I).

The mean hospital stay was slightly longer for women in the control group (2.9 days) than for those in all three exercise groups (range 2.2 to 2.6 days) ($p < 0.0001$), despite the fact that the mean parity was higher in the control group (Table I).

Maternal and fetal heart rates were monitored during one exercise session in the twenty-eighth week of gestation and another in the thirty-eighth week, for women who proceeded that far in the conditioning program. Maternal heart rates were appropriately elevated during exercise, while fetal heart rates remained normal in all cases. At no time was fetal bradycardia observed as a result of the aerobic or anaerobic exercise stimulus.

When participants in the study were surveyed at 6 weeks post partum regarding their subjective responses to the exercise sessions, all reported that the conditioning program gave them an improved self-image as well as a decrease in the common discomforts of pregnancy as long as they participated. Those who stopped the program for more than 2 weeks had a return of many of their aches and pains (especially low-back pain) and self-image declined. All patients stated that the program relieved tension. Patients who continued their conditioning until the onset of labor thought the exercise was beneficial during labor and delivery. It was the impression of the multiparous patients that their recovery period was more rapid than that after previous pregnancies.

Comment

Strenuous exercise has many potential dangers during pregnancy, for example, hyperthermia, dehydration, hypoxia, "energy drain," and possible injury to the expectant mother and/or developing fetus. It is not surprising then that the practicing obstetrician in this litigious society tends to be conservative about prescribing exercise regimens. Of particular concern to most obstetricians is undetected fetal hypoxia.

One cause of fetal hypoxia could be excessive catecholamine production associated with maternal exercise stress. Rauramo et al.[7] have shown that pregnant women respond to induced exercise with signficant increases in both epinephrine and norepinephrine. In experiments on rhesus monkeys, Adamsons et al.[8] demonstrated that either epinephrine or norepinephrine can produce severe asphyxia of the fetus when given in amounts that elicit a distinct increase in maternal blood pressure. However, physical conditioning can decrease the catecholamine response to a given exercise stress.[9] Therefore it may be potentially beneficial to condition the expectant mother before the onset of the greatest physical stress she and her fetus will experience during the course of the pregnancy—labor and delivery. Animal studies suggest that such conditioning is beneficial; blood diversion away from the uterus in the pregnant sheep and guinea pig is less when these animals have undergone physical training.[10, 11]

Our conditioning program was designed in part to control catecholamine production and thereby minimize its effect on the uterine vasculature during labor. Variables in the exercise protocol that were controlled included the intensity, duration, and type of exercise, the temperature and humidity of the exercise environment, and the diet. We believe that supervision of the training experience is important because pregnant patients are generally unaware of what factors elevate the catecholamine response to exercise and fetal hypoxia is a realistic concern.

A major objective of our conditioning program was to minimize exaggerated postural changes of pregnancy, such as thoracic kyphosis with secondary forward head position and excessive lumbar lordosis. These can occur when muscle groups become shortened or lengthened during gestation, causing a state of imbalance with opposing muscles and producing faulty alignment and deformity. We performed ongoing individual evaluations to identify muscle groups that required strengthening or increase in flexibility in order to compensate for increased mass in abdominal and breast tissue and thereby maintain normal posture.

We believe that pregnant women should not undertake strength-training without supervision because most are unaware of the progressive nature of the postural changes of pregnancy. Unsupervised training may well aggravate lordosis and other symptoms. The rectus abdominis muscle particularly requires strengthening because it is the only longitudinal anterior muscle that controls the degree of lumbar curvature. Failure to strengthen this muscle during pregnancy and to attempt to limit lumbar lordosis and its associated complaints is likely to invite many prenatal aches and pains. More significantly, a previous term pregnancy is one of the most important risk factors for lumbar disc disease.[12] This could be related to failure of the pregnant patient to limit the degree of lordosis during pregnancy and the resulting damage that occurs because of increasing axial compression and/or sheer forces on the lumbar disc.

Goodlin and Buckley[13] have stated that one criterion for judging whether exercise has adverse effects on pregnancy is to compare the size of newborn infants of exercising and nonexercising mothers of similar socioeconomic level. Our data indicated that birth weights were approximately 150 gm higher for babies of women in the high-exercise group than for babies of control mothers (all mothers in our study were middle or upper middle class). In a study of women who followed a running program throughout pregnancy, Clapp and Dickstein[14] found an opposite phenomenon—women who continued exercising to term had offspring whose mean birth weight was 500 gm less than that of offspring whose mothers stopped exercise before the twenty-eighth week of gestation. However, the patients in their report probably consumed more energy during jogging than did the women in our study, whose aerobic exercise consisted of cycling. Oxygen requirements and therefore energy consumption are higher during a weight-bearing exercise such as jogging than during the more mechanically efficient activity of cycling. Thus the attainment of equal degrees of cardiovascular fitness in these two activities requires significantly more caloric expenditure in the case of jogging. In our study, the prescribed length of cycling in controlled environmental conditions should have been minimally energy-draining.

Because of the retrospective nature of this study, no random assignment of subjects to groups was performed, and the numbers of subjects varied from group to group. The most obvious potential problem with retrospective studies of this type is selection bias. Thus undetected intervening variables may have contributed to the superior pregnancy outcomes in our high-exercise group. Possibly the subjects who participated in the conditioning program were more fit to begin with and therefore more predisposed to carry out the training program. However, only four of the 61 women in our high-exercise group—the group clearly demonstrating the best pregnancy outcomes—had a regular exercise history before entering the conditioning program. More controlled experiments are needed to scrutinize the variables that contribute to the impact of physical conditioning on pregnancy outcome.

In no instance did our conditioning program have a negative effect on either the mother or the fetus. This should reassure obstetricians who wish to consider exercise training programs for their pregnant patients. The only minor complaint that some women had was that the treadmill warm-up grew uncomfortable as term approached. For this reason and because of our growing awareness of the need to avoid the effects of gravitational pull on the muscles of the anterior abdominal wall, we discontinued the treadmill warm-up and substituted bicycling. The subjective responses of women in the study to the conditioning program were uniformly positive. They reported that the exercise sessions enhanced their self-image, reduced many minor complaints of pregnancy, and satisfied their need or desire for exercise.

Each pregnant patient has a unique array of modifying factors that makes the individualization of exercise prescription critical. In addition to her physiologic needs, the woman's medical history, vocational and recreational activities, financial and time constraints, and psychological attitudes toward exercise must be considered. Because of the progressive nature of the physical changes of pregnancy, the obstetrician needs to reevaluate the exercise prescription at regular intervals throughout the pregnancy.

We thank Barbara G. Cox for her assistance in the preparation of this manuscript.

Evaluation of a perinatal grief support team

Marian F. Lake, R.N.C., M.P.H., Thomas M. Johnson, Ph.D., Jane Murphy, M.P.A., and Robert A. Knuppel, M.D., M.P.H.

Tampa, Florida

An analysis of the effects of intervention from a perinatal grief support team was begun in 1982. Seventy-eight women experiencing stillbirth or early perinatal death were randomly assigned to either the grief support team's protocol of care or to the control group who received routine hospital care. Assessment was carried out on 34 participants, 16 from the control group and 18 from the treatment, 6 months after delivery. A three-part self-administered, self-rating grief index questionnaire was used. There was no statistical difference on overall grief scores between the two matched groups. The treatment group reported significantly lower scores than the control group on the two grief subscales of anger-hostility and physical symptoms. Women who reported more life changes before the perinatal death tended to have fewer problems with the symptomatology of grief. Social support was an important variable in explaining grief symptomatology. Women reporting low levels of social support who were in the treatment group had significantly lower mean scores on the grief subscales of anger-hostility, somatic experience, physical symptoms, and problems with vigor. (AM J OBSTET GYNECOL 1987;157:1203-6.)

Key words: Stillbirth, grief support, perinatal bereavement

The crisis of perinatal death has received attention in the medical literature during the last decade. Health care providers have begun to recognize the need for emotionally supportive care after perinatal death and have implemented programs of active intervention designed to provide that care.

Evaluation of the efficacy of structured perinatal grief counseling programs is singularly lacking. Forrest et al.[1] provide one evaluation of a group of 50 families who had experienced a perinatal death. Interviews and self-rating scales administered at 6 and 14 months after the death revealed that the unsupported group demonstrated a significantly greater number of psychiatric disorders. Lacking any further documentation of the efficacy of such a program, we undertook an evaluation of a perinatal bereavement intervention program.

A program of active intervention for families experiencing perinatal death was initiated by us at a large tertiary perinatal center serving a predominantly indigent population in west central Florida. As previously

Table I. Objectives of perinatal grief crisis intervention

Before discharge	*4-6 wk post partum*	*4-6 mo post partum*
1. Provide basic human comfort and support	1. Share preliminary autopsy report	1. Share final autopsy results
2. Help make loss real	2. Assess patient's progress	2. Reassess emotional progress
3. Encourage expression of emotion	3. Facilitate emotional release	3. Reassess social support
4. Encourage open communication among family members	4. Describe incongruent grieving	4. Explore possible problems in marital or sexual relationship
5. Prepare for encounters in community	5. Assess couple's progress	5. Schedule anniversary appointment
6. Assess response in preparation for future meetings	6. Discuss local support groups	
7. Record information	7. Assess local support	
8. Schedule 4-6 wk appointment	8. Discuss plans for subsequent pregnancies	
	9. Schedule 4-6 mo appointment

Age at last pregnancy	26.00	22.43	−2.11	0.046

described, the program focused on a series of timely meetings with the patient, her family, and one or more members of the perinatal grief support team.[2] Two meetings occurred before discharge, another at 4 to 6 weeks after discharge, and a third at 4 to 6 months. Objectives were established for each of those meetings (Table I). A perinatal nurse and perinatal social worker functioned as primary team members.

Methods

Seventy-eight women experiencing perinatal death were enrolled in the study plan between June 1982 and June 1984. Each participant provided informed consent and was then randomly assigned to either treatment group or control group. For the purpose of this study, perinatal death was defined as the delivery of a fetus ≥20 weeks' gestation or weighing at least 500 gm that was either stillborn or died within 2 hours of birth. Intervention was defined as the implementation of the meeting schedule and objectives of the perinatal grief support team. The control group received no intervention from the grief support team.

Both groups were assessed 6 months after delivery by means of a grief index questionnaire. The questionnaire contained (1) questions designed to retrieve demographic, social environment, and health care experience data; (2) the Homes and Rahe social readjustment rating scale,[3] a 39-item inventory that surveyed recent life events; (3) an adaptation of the grief experience inventory.[4] The grief experience inventory, a 63-item inventory that is divided into 16 subscales, asked respondents to agree or disagree with symptoms of grief via a four-point Likert scale.

Participants, after having been contacted by a research assistant who was blinded to the randomization code, were asked to complete the self-administered tool.

Results

Thirty-four of the 78 participants (43.5%) were able to be located approximately 6 months after delivery. Follow-up questionnaires were completed on these 34 patients (16 white, 18 black), 16 from the control group (eight white, eight black) and 18 from the treatment group (eight white, 10 black).

In order to assess comparability of treatment and control groups, *t* tests were run on the means for the demographic variables of age, education, and data on obstetric history (Table II). The treatment and control groups are not significantly different on any variable except age at previous pregnancy. There is also no sampling bias with respect to race nor is race a significant variable in any of the analyses that follow.

Assessment of grief experiences. Treatment and

Table III. Comparison of grief experience scores* of women receiving grief counseling and a control group at 6 weeks after stillbirth

Table IV. Analysis of covariance to assess relationship of grief counseling and life changes before death on grief symptoms

	Main effects of treatment		*Effects of life changes before death*		
Grief subscale	*F*	*Significance of F*	*F*	*Significance of F*	R^2
Physical symptoms	10.40	0.004	14.10	0.001	0.527
Anger-hostility	7.97	0.010	8.96	0.007	0.437
Social isolation	5.25	0.032	6.61	0.017	0.350

control group mean scores on the grief experience inventory were compared by means of *t* tests. Comparisons were made on total grief scores as well as subscale scores.

There was no statistically significant difference between the treatment and control groups on overall grief score. The *t* tests comparing mean scores on grief subscales confirmed that a statistically significant difference ($p < 0.05$) exists between the treatment and control groups on the two subscales "physical symptoms" ($p = 0.035$) and "anger-hostility" ($p = 0.035$) (Table III). Patients treated with the perinatal grief counseling protocol experience less difficulty with such physical complaints as diarrhea or constipation, tense neck and shoulders, frequent headaches, dryness of the mouth and throat, and aches and pains as well as with such psychological manifestations of grief as irritability, angry feelings, and resentfulness at the activities of others.

Life stress and grieving. To test the hypothesis that life stress might exacerbate this grief reaction, scores on the Homes and Rahe social readjustment rating scale were calculated for each subject for two periods of time: in the year before and in the time since the death.

To evaluate the relative effects of both grief counseling and life changes on symptomatology of grief, analysis of covariance procedures were used to simultaneously assess the effects of life changes and grief counseling program treatment on those grief subscales that appear to be most significantly related to treatment ("anger-hostility," "physical symptoms," and "social isolation"). When life change in the year before the death is included as a covariate with treatment group status (Table IV), the main effects of treatment remain significant for "physical symptoms" ($F = 10.40$, $p = 0.004$) and "anger-hostility" ($F = 7.97$, $p = 0.010$) and also become significant for "feelings of social isolation" ($F = 5.25$, $p = 0.032$).

Effects of social support on grief and grief counseling. Analysis of questionnaire items designed to assess social support from family, friends, and the father of the baby was carried out. These seven items, taken together, constitute a scale with an alpha reliability co-

efficient of 0.843, a mean score of 19.41, and a range from 8 to 24.

Analysis of covariance procedures to control for the effect of support reveal that, when support is controlled for, treatment effects on "anger-hostility, "physical symptoms," and "feelings of social isolation" become statistically insignificant ($p = 0.29$, 0.18, and 0.09, respectively), suggesting that support is an important variable in explaining grief symptomatology.

Evaluation of the effect of treatment on women reporting low levels of social support, defined as a score below the median of 20, was done. Women with low support scores in both the treatment and control groups were selected out with t tests run on the differences in mean grief scale scores. In women with low support who received counseling, mean scores were significantly lower than for those who were in the control group for "anger-hostility" ($t = 2.04$, $p = 0.059$), "social isolation" ($t = 2.20$, $p = 0.043$), "somatic experience" ($t = 2.59$, $p = 0.022$), "physical symptoms" ($t = 2.07$, $p = 0.059$), and "problems with vigor" ($t = 2.36$, $p = 0.030$).

Comment

In this analysis of the effects of a perinatal grief counseling program on the grief process, several important findings have direct applications for clinicians working in obstetrics. The evaluation has demonstrated that implementation of a grief counseling protocol can reduce aspects of the troubling symptoms of grief after stillbirth with particular effectiveness in certain groups of women. The evaluation has identified women who are most likely to benefit from intervention by a grief support team.

All findings must be evaluated in light of several major methodologic shortcomings. First, all of the questionnaire data were collected 6 months after the deaths of babies and many of the questions demanded retrospective recall by patients. Such an approach is well known to be problematic, as intervening events may selectively enhance or impede recall. Second, our sample is quite small; indeed, this research ought more properly be thought of as a pilot study.

Nonetheless, these data suggest that women who received perinatal grief counseling experienced fewer problems with certain types of grief symptoms. While some of this difference between treatment and control patients may be due to the grief counseling protocol, it is also influenced by other factors.

Our data would suggest, for example, that the amount of life changes a woman has in the year before a stillbirth influences grief symptoms. When we control for life changes and social support, treatment with the protocol predicts fewer problems with anger-hostility and physical symptoms associated with grieving. In those women with low social support, treatment is particularly effective, with women who receive grief counseling reporting less difficulty with feelings of social isolation, anger-hostility, somatic experience, physical symptoms, vigor, and death anxiety than their control subjects who also have low social support.

Clinical implications inferred from this study include the following: (1) Intervention by a grief support team is likely to reduce the grieving woman's anger and hostility; (2) intervention by a grief support team is likely to reduce the physical symptoms characteristic of normal grief; (3) intervention by a grief support team is particularly effective for women who perceive themselves to have low levels of social support. When grieving women receive attention to their emotional needs, particularly women with minimal social support, they are less likely to experience angry feelings and resentfulness regarding the death of their baby. Not uncommonly, health care providers, for a variety of reasons, avoid spending time with grieving patients. This evaluation suggests that that lack of attention may leave women with feelings of anger, hostility, and resentfulness.

Women are frequently troubled by the normal physical symptoms associated with grieving (for example, gastrointestinal distress, insomnia, loss of appetite, headache). Frequent calls and/or visits to the clinician's office are not uncommon as a result. Busy practitioners may in turn be frustrated and angered by a patient they perceive to be a "chronic complainer." This evaluation suggests that intervention by a bereavement team may relieve or decrease the incidence of these troublesome symptoms.

For health professionals working with women who suffer stillbirths, our data would suggest that those women who perceive themselves to have little support from families and friends and who have had very little life change in the year before the deaths of their babies would seem to be at particular risk for troubling grief symptoms and are also those who would most benefit from a special grief counseling program.

Local peritoneal factors: Their role in infertility associated with endometriosis

Sherif G. Awadalla, M.D., Chad I. Friedman, M.D., Amin U. Haq, M.D., Sung I. Roh, M.D., NeeOo W. Chin, M.D., and Moon H. Kim, M.D.

Columbus, Ohio

In order to detect peritoneal abnormalities that could account for infertility associated with endometriosis, 122 infertile individuals were studied at the time of laparoscopy for diagnostic purposes or for in vitro fertilization. Four groups were defined: group 1, laparoscopy without endometriosis; group 2, laparoscopy with endometriosis; group 3, in vitro fertilization without endometriosis; and group 4, in vitro fertilization with endometriosis. Mean peritoneal fluid volume was greater, although not significantly so, in group 4 (29.0 ± 6.6 ml, mean ± SEM) than in group 3 (18.2 ± 2 ml). The concentration and total number of pelvic macrophages were similar for groups 1 and 2. The total number of pelvic macrophages was increased in group 4 ($16.9 \pm 4.2 \times 10^6$) versus group 3 ($10.0 \pm 1.8 \times 10^6$) ($p = 0.08$). The mean sperm phagocytosis in vitro did not differ among the four groups studied. Interleukin 1 activity within the peritoneal fluid and the in vitro interleukin 1 production rate did not differ between individuals with and without endometriosis. Peritoneal fluid and macrophage supernatants from individuals with endometriosis were not embryotoxic when studied in an in vitro mouse embryo system. (AM J OBSTET GYNECOL 1987;157:1207-14.)

Key words: Endometriosis, infertility, macrophages, interleukin 1

Although endometriosis is a common finding in a population of infertility patients, there is as of yet no clear cause-and-effect relationship between these two disease entities. When the endometriosis is severe and extensive pelvic adhesions are present, one can implicate a mechanical factor. However, when the endometriosis is mild or moderate and is present without concomitant pelvic adhesions, the mechanism of the infertility associated with endometriosis is not well understood. Indeed it has even been postulated that endometriosis may not cause infertility but may be a result of chronic infertility.

Recently much controversy has been focused on local peritoneal factors and their role in infertility associated with endometriosis. There is some evidence that macrophages may be present in higher concentrations, in higher total numbers, or in a more activated form in patients with endometriosis.[1-3] Peritoneal macrophages from patients with endometriosis have been shown to phagocytize sperm more readily than controls in vitro.[4] Higher prostaglandin concentrations have been demonstrated within peritoneal fluid in individuals with endometriosis by some investigators.[1,5] This derangement of peritoneal fluid chemistry may impair tubal motility or impede the development of the early embryo.

The present investigation deals with pelvic macrophage content and function in infertile patients with and without endometriosis. Sperm phagocytosis was also assessed by an in vitro assay. Interleukin 1 activity in the peritoneal fluid and production rate in vitro were determined. A two-cell mouse embryo system was also used to determine if peritoneal fluid from patients with endometriosis is toxic to the early mammalian embryo.

Material and methods

Subjects. The study population consisted of 122 infertile patients. Seventy-six were studied during diagnostic laparoscopy for infertility: Group 1 (n = 41) was without endometriosis whereas group 2 (n = 35) displayed active endometriosis. Forty-six patients were studied during laparoscopy for egg retrieval and in vitro fertilization: Group 3 (n = 32) was without endometriosis whereas group 4 (n = 14) displayed active endometriosis. All patients had undergone a complete infertility investigation including analysis of semen, basal body temperature graphing, timed progesterone determination, hysterosalpingography, and postcoital testing. Patients with a history of endometriosis but no active disease at the time of laparoscopy were excluded from the study.

Sample collection. Laparoscopy was performed by one of the authors with the patient under general anesthesia. A careful search for endometriosis was made

by use of a double-puncture technique. Endometriosis was staged according to the original American Fertility Society classification. Peritoneal fluid was aspirated from the anterior and posterior cul-de-sacs with a hollow cannula. This was accomplished before placement of the patient in the Trendelenburg position. The peritoneal fluid was then placed into sterile heparinized tubes in order to avoid macrophage adherence to glass. The fluid was immediately transported to the laboratory. Its volume was determined to the nearest 0.5 ml and the fluid was centrifuged at 500 × g for 10 minutes. The supernatant was then removed and used for analysis on the same day or frozen at −20° C until later assay. The cell pellet was then resuspended in 4 ml of phosphate-buffered saline solution and recentrifuged at 500 × g for 10 minutes. The supernatant was removed and the cells resuspended in 1 ml of Ham's F-10 medium (Gibco, Grand Island, New York) with 10% fetal calf serum (Sigma, St. Louis, Missouri) supplemented with 20 μg/ml penicillin and 12.5 μg/ml streptomycin. Twenty microliters of the suspension was then diluted 1:10 with phosphate-buffered saline solution and stained with 1% trypan blue. With a hemacytometer, five large (1 mm) squares were counted and the concentration of viable leukocytes was determined. A cytospin preparation of the cell suspension was made, fixed in alcohol, and stained with Giemsa. A differential count was then performed. Macrophages can be recognized because of their large size and vacuolization.

Sperm phagocytosis. Sperm was obtained from fertile donors who were participants in an artificial insemination program. Fresh or cryopreserved sperm was used. Cryopreserved sperm displayed a motility of 40% to 60%. Fresh sperm typically displayed 60% to 80% motility. Sperm was doubly washed with Ham's F-10 medium with 10% fetal calf serum and the final suspension was adjusted to a concentration of 1×10^7 sperm per milliliter. The macrophage suspension was adjusted to a concentration of 4×10^6 macrophages per milliliter. One tenth milliliter of the macrophage suspension was placed within a microtiter chamber. The macrophages were allowed to attach for 2 hours. Each well was then washed with Ham's F-10 medium in order to remove nonadherent cells. Nonadherent cells consisted primarily of lymphocytes, erythrocytes, and nonviable macrophages. The number of viable macrophages within the supernatant was consistently ≤10% of the originally plated number. The number of adherent cells per well did not differ among the groups studied. One hundred microliters of sperm was added to each of three chambers with macrophages and to each of three empty chambers to be used as controls. The samples were incubated for 20 hours. The supernatant was then harvested by pipetting the fluid up and down five times. The sperm were counted in a hemacytometer. The percent phagocytosis is expressed as:

$$100 - \frac{\text{number of sperm in supernatant of experimental well}}{\text{number of sperm in control supernatant}} \times 100$$

The intra-assay variability was 7%.

Interleukin 1 assay. Interleukin 1 activity within the peritoneal fluid and the in vitro production rate of interleukin 1 were determined. When peritoneal fluid levels were determined, the peritoneal fluid was stored at −20° C until the day of the assay. When interleukin 1 levels in culture media were determined, 1×10^5 macrophages were cultured in a microtiter well with 0.2 ml of Ham's F-10 medium and 10% fetal calf serum. The culture medium was harvested at 20 hours and frozen at −20° C until assay. In a separate experiment, macrophage production of interleukin 1 was stimulated with 20 μg/ml of lipopolysaccharide.

Interleukin 1 assay was performed as described by Lachman et al.[6] Male CD-1 mice, 4 to 8 weeks old (Charles River, Wilmington, Massachusetts), were put to death and the thymuses were removed and pressed through a wire mesh aseptically. The debris was allowed to sediment and the thymocytes were washed and resuspended to a concentration of 1×10^7/ml in medium RPMI 1640 plus 100 μ/ml penicillin, 100 μ/ml streptomycin, 0.3 mg/ml glutamine, 2.5×10^{-5} mol/L 2-mercaptoethanol, and 5% AB serum. Cultures were established in microtiter plates with each well containing 1×10^6 cells. Each experiment was performed in triplicate. Ten microliters of culture medium to be tested or peritoneal fluid was added to each well. Each experiment was controlled. Controls consisted of Ham's F-10 medium with 10% fetal calf serum. Cultures were incubated at 37° C with 5% carbon dioxide and pulsed after 48 hours with 0.5 μCi tritium-labeled thymidine (New England Nuclear, Boston, Massachusetts). Cultures were harvested at 72 hours onto filter paper with an automatic harvester. The incorporated radioactivity was measured by means of a liquid scintillation counter. Interleukin 1 activity was expressed as average counts per minute.

Mouse embryo assay. Two-cell mouse embryos were used as the starting point of the assay. CB_6F_1 mice, both male and female (Charles River), were used. This is a hybrid cross between Balb/c and c57B1/6 strains and have provided two-cell embryos whose rate of development to blastocyst is ≥70%. Ovulation was induced with 7.5 IU of pregnant mare serum intraperitoneally on the first day of estrus. This was followed by 7.5 IU human chorionic gonadotropin intraperitoneally 48 hours later. On the day of human chorionic gonado-

Table I. Characteristics of the study groups

Group	n	Age (yr) (mean ± SEM)	Duration of infertility (yr) (mean ± SEM)	% with primary infertility
1	41	29.7 ± 1.1	3.0 ± 0.4	46
2	35	30.7 ± 1.2	3.5 ± 0.5	74
3	32	31.2 ± 1.0	5.0 ± 0.5	44
4	14	32.7 ± 1.1	5.2 ± 0.5	86

Table II. Total content and concentration of pelvic macrophages

Group	n	Concentration of macrophages × 10^5/ml (mean ± SEM)	Total macrophages × 10^6/case (mean ± SEM)
1	41	11.07 ± 1.3	8.16 ± 1.1
2	35	12.9 ± 1.8	9.79 ± 1.3
3	32	6.06 ± 0.65	10.0 ± 1.8
4	14	6.61 ± 1.4	16.9 ± 4.2

tropin administration the female mice were mated with male mice of established fertility in a 1:1 ratio. Forty-eight hours later the female mice were put to death by cervical dislocation and the fallopian tubes were dissected. Under the dissecting microscope, the fallopian tubes were incised and two-cell mouse embryos were pipetted into one dish containing Ham's F-10 medium. All embryos were pooled before random allocation to experimental wells. During each trial, equal numbers of endometriosis and nonendometriosis specimens were analyzed. Experiments in which the control result was less than 70% blastocyst formation were repeated. Control wells consisted of Ham's F-10 medium with 10% fetal calf serum. For testing of peritoneal fluid, wells with 10% peritoneal fluid were prepared. For testing macrophage supernatants, 0.5×10^5 macrophages were placed in a microtiter well and allowed to adhere for 2 hours; then the plates were washed with Ham's F-10 medium. One hundred microliters of Ham's F-10 medium with 10% fetal calf serum or Ham's F-10 medium with 10% fetal calf serum containing 10^{-5} mol/L indomethacin or 20 μg/ml lipopolysaccharide was then added to the adherent macrophages. After 24 hours 100 μl of the supernatant was transferred to a new well and to this was added 100 μl of fresh Ham's F-10 medium with 10% fetal calf serum. To each well eight to 10 two-cell mouse embryos were added. A layer of paraffin oil was used to cover the wells and the embryos were incubated for 72 hours. The numbers of blastocysts and degenerate embryos were then determined under phase contrast microscopy.

Statistics. Statistical analysis was conducted by use of the unpaired *t* test and the Mann-Whitney U test. Analysis of variance was conducted to evaluate the mouse embryo experiment and the sperm phagocytosis experiment.

Results

Seventy-six patients were studied during diagnostic laparoscopy for infertility. Within group 2, 77% of patients displayed mild endometrosis and the remainder displayed moderate endometriosis. Seventy-three percent of patients in group 1 displayed pelvic adhesions whereas the remainder had normal pelvic anatomy and their infertility could be explained on the basis of ovulatory dysfunction, cervical factor, or male factor. Forty-six patients were studied during laparoscopy for egg retrieval and in vitro fertilization. Within group 4, 79% displayed mild endometriosis and the remainder displayed moderate endometriosis. Seventy-four percent of patients in group 3 underwent the procedure because of tubal disease; in the remainder, the indication was male factor or cervical factor infertility. Table I details general characteristics of the four study groups.

Peritoneal fluid volume was found to be increased in the luteal phase as compared with the follicular phase in both and groups 1 and 2, as shown in Fig. 1. The mean peritoneal fluid volume was 6.78 ± 0.92 ml (±SEM) for group 1 individuals in the follicular phase (n = 18) compared with 12.9 ± 3 ml for group 1 individuals (n = 19) in the luteal phase (p = 0.05). The mean peritoneal fluid volumes in the follicular (n = 19) and luteal phases (n = 13) for group 2 were 8.09 ± 1 and 17.2 ± 5.3 ml, respectively (p = 0.04). The overall mean peritoneal fluid volume for group 2 was 9.36 ± 0.99 versus 9.59 ± 1.5 for group 1 (NS). No statistically significant difference in peritoneal fluid volume was found between groups 1 and 2 when analysis was restricted to either the follicular or the luteal phase of the menstrual cycle. When group 2 was analyzed on the basis of the stage of endometriosis, the peritoneal fluid volume was 9.44 ± 1.2 ml for 27 patients with mild endometriosis and 9.09 ± 1.2 ml for eight patients with moderate endometriosis (NS); neither value was significantly different from the value in group 1 (9.59 ± 1.5 ml, n = 41). The mean peritoneal fluid volume for group 4 patients was higher than for group 3 patients (29.0 ± 6.6 versus 18.2 ± 2 ml). However, this difference was not statistically significant (p = 0.10).

Table II displays data for the concentration and total numbers of pelvic macrophages. No statistically significant differences were found when the concentration or total number of pelvic macrophages was compared between groups 1 and 2. When patients with mild endometriosis were compared with those with moderate

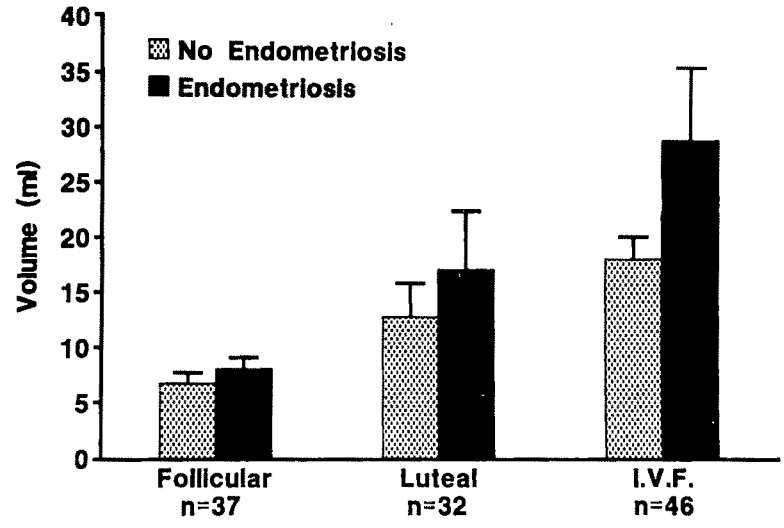

Fig. 1. Peritoneal fluid volume (mean ± SEM) during various phases of the menstrual cycle.

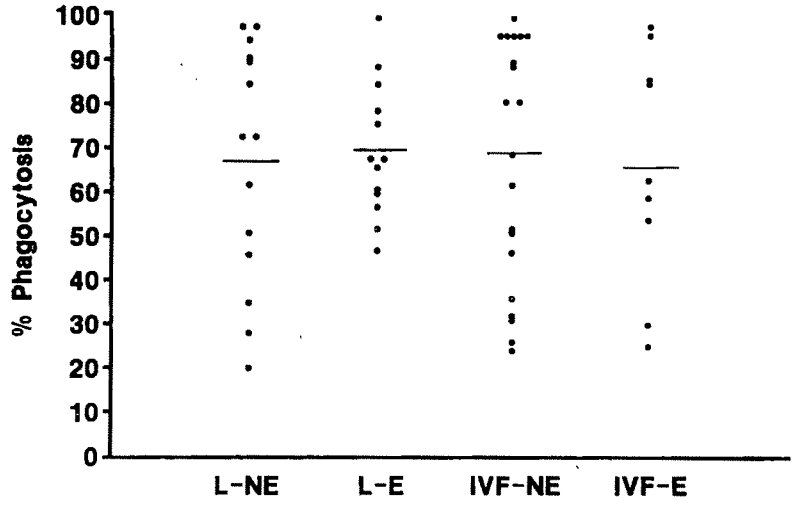

Fig. 2. In vitro sperm phagocytosis in patients undergoing laparoscopy with no endometriosis (group 1, *L-NE*), laparoscopy with endometriosis (group 2, *L-E*), in vitro fertilization with no endometriosis (group 3, *IVF-NE*), and in vitro fertilization with endometriosis (group 4, *IVF-E*).

endometriosis within group 2, no significant differences were discovered in the mean concentration or total number of pelvic macrophages. For groups 3 and 4, no difference was found in the concentration of pelvic macrophages. The total content of macrophages was 16.9 ± 4.2 × 10^6 (± SEM) in group 4 patients and 10.0 ± 1.8 × 10^6 in group 3 patients (p = 0.08).

The results of the sperm phagocytosis assay for the four groups studied are shown in Fig. 2. The mean phagocytosis was 69.8% ± 4.3% for group 2 patients (n = 13) versus 67.5% ± 7.3% for group 1 patients (n = 14) (NS). The mean sperm phagocytosis was 66.2% ± 9% for group 4 patients (n = 9) versus 69.2% ± 6.3% for group 3 patients (n = 20) (NS). The mean sperm phagocytosis was 68% ± 5.4% for patients with mild endometriosis (n = 16) compared with 69.3% ± 7.4% for individuals with moderate endometriosis (n = 6) (NS); neither of these values differed significantly from those of group 3. Very little nonspecific adherence of sperm to plastic was noted. Initial and final counts in control wells varied by less than 5%. Since the assay measures phagocytosis and adherence of sperm to macrophages, phase contrast microscopy after incubation and removal of supernatant for counting was performed. Little adherence of sperm was noted, suggesting that the majority of assayable activity is phagocytosis rather than adherence. Sperm phagocytosis was relatively rapid with most of the phagocy-

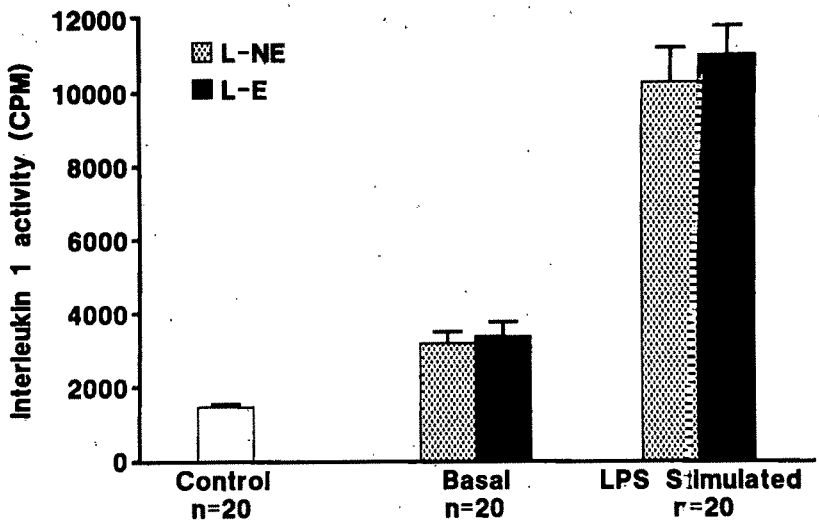

Fig. 3. In vitro production rate of interleukin 1 expressed as mean ± SEM for the group 1 *(L-NE)* and group 2 *(L-E)*. *LPS* = Lipopolysaccharide.

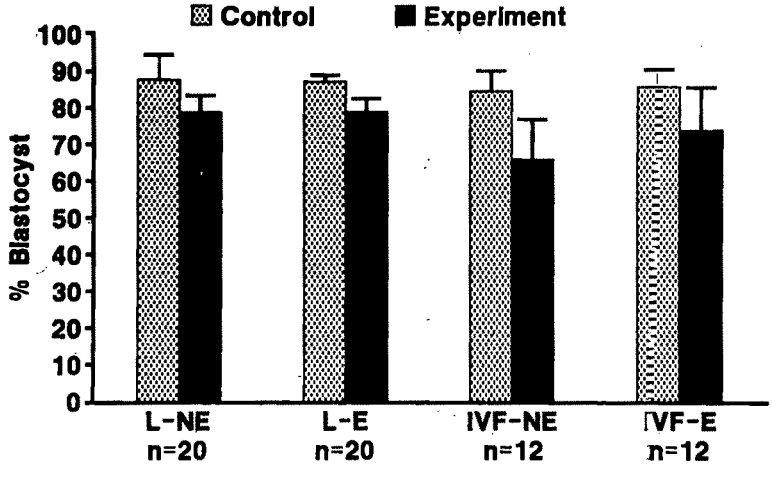

Fig. 4. Effect of peritoneal fluid on mouse embryo development in vitro. Results expressed as mean ± SEM for the following groups: laparoscopy with no endometriosis (group 1, *L-NE*); laparoscopy with endometriosis (group 2, *L-E*), in vitro fertilization with no endometriosis (group 3, *IVF-NE*), and in vitro fertilization with endometriosis (group 4, *IVF-E*).

tosis completed by 6 hours. At 6 hours of incubation 85% ± 5.6% of the phagocytic activity observed at 20 hours had occurred (n = 10).

Peritoneal fluid interleukin 1 levels were determined in a single assay for 14 patients in group 1 and 14 patients in group 2. Peritoneal fluid interleukin 1 activity was 3233 ± 468 and 3331 ± 600 cpm for groups 1 and 2, respectively (NS). Fig. 3 displays the interleukin 1 activity in macrophage supernatants after 20 hours of in vitro culture. No difference was found in the in vitro production rate of interleukin 1 by macrophages from groups 1 and 2 under basal or lipopolysaccharide-stimulated conditions. Also there did not appear to be a statistically significant difference in peritoneal fluid levels or production rates of interleukin 1, depending on the proliferative versus the secretory phase of the menstrual cycle.

The mouse embryo experiment was conducted with peritoneal fluid in 64 cases. Fig. 4 displays the results. Since each experiment was controlled, each result is listed with its own control consisting of Ham's F-10 medium with 10% fetal calf serum. The mean percent of two cells developing to the blastocyst stage was 79.2 ± 4.4 for group 1 versus 79.3 ± 3.5 for group 2 and 87.7 ± 1.61 for the control group. This difference was not statistically significant. The mean percent of two cells developing to the blastocyst stage was 66.3 ± 10.8 for group 3 versus 73.8 ± 11.7 for

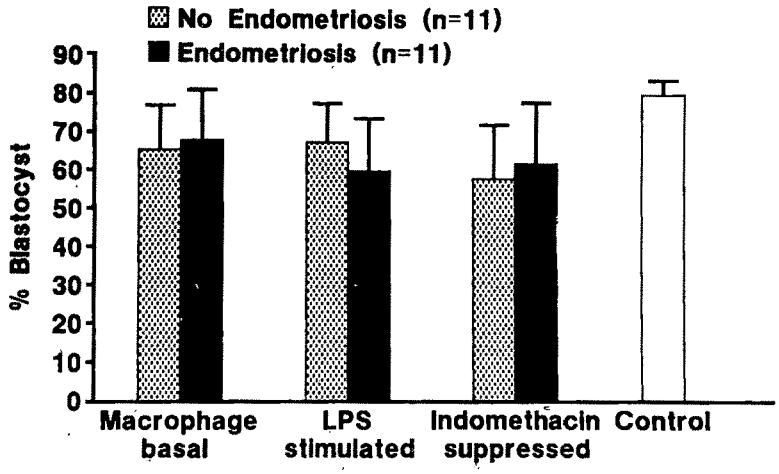

Fig. 5. Effect of macrophage supernatants on mouse embryo development in vitro, expressed as mean ± SEM.

group 4 and 85 ± 4.59 for the control group. This difference also was not statistically significant.

Culturing of mouse embryos in macrophage supernatants was accomplished in 11 patients with and 11 patients without endometriosis. Fig. 5 displays the results of these experiments. No statistically significant differences in the rate of development to the blastocyst stage were found when each of the experimental groups was compared with the control group. Also no statistically significant differences between any of the experimental groups were found.

Comment

Although endometriosis is a frequent finding in the setting of infertility, the pathophysiologic characteristics of infertility in the setting of endometriosis are not well defined. Recently much attention has focused on local peritoneal factors and their role in infertility associated with endometriosis. Analysis of peritoneal fluid volumes is hampered by variance of the volume as a function of the menstrual cycle. Also it is important to differentiate whether patients with endometriosis are compared with normal fertile individuals or with other infertile individuals without endometriosis. Oak et al.[7] and Drake et al.[8] have noted an increased volume of peritoneal fluid in patients with endometriosis when compared with fertile control subjects. Numerous other investigators have reported no difference in peritoneal fluid volume in individuals with endometriosis when compared with other infertile patients.[9, 10] Peritoneal fluid volumes within the context of this investigation were not found to be significantly different when infertile patients with and without endometriosis were compared at the time of diagnostic laparoscopy. At the time of in vitro fertilization, the mean peritoneal fluid volume was higher in patients with endometriosis but this difference was not statistically significant ($p = 0.10$).

Recently much attention has centered on pelvic macrophages as a possible mediator of infertility in patients with endometriosis. Macrophages have been reported to consistently represent at least 90% of peritoneal leukocytes.[4] Macrophages have also been demonstrated within the lumen of the fallopian tube. Therefore they have access to the microenvironment of fertilization and early embryonic development. Verifying differences in macrophage numbers or function would be an important step in implicating macrophage dysfunction as causative in infertility associated with endometriosis. Within the four groups studied no significant differences were found in macrophage concentrations or total pelvic content. The mean total pelvic macrophage content was higher for group 4 than group 3 (16.9 ± 4.2 versus 10.0 ± 1.8) but this difference was not significant. It is to be emphasized that our control group consisted of infertile patients without endometriosis. Badawy et al.[1] demonstrated increased numbers of peritoneal macrophages in patients with endometriosis when compared with infertile control subjects ($n = 102$). Haney et al.[2] demonstrated increased macrophage counts in women with endometriosis when compared with normal fertile control subjects or other infertile individuals with endometriosis ($n = 32$). Halme et al.,[3] in 1983, reported no statistically significant differences in pelvic macrophage concentration when comparing infertile women with endometriosis and either fertile or infertile control subjects ($n = 66$). However, they did report evidence of increased macrophage activation in patients with endometriosis. In 1984, Halme et al.[11] again reported the finding of similar or lower concentrations of pelvic macrophages in individuals with endometriosis when compared with

fertile control subjects (n = 107). From this conflicting information one might suggest that the populations studied are probably not homogeneous. Perhaps some patients with endometriosis do possess an increased total number of macrophages since a trend toward this was found in this investigation.

Macrophages originate in the bone marrow and circulate in the blood in the form of monocytes. They migrate to various sites of the body, differentiate into macrophages, and serve as an immunologic line of defense for the human body. Macrophages in particular are highly phagocytic and normally remove foreign particles and cellular degradation products from the body. Muscato et al.[4] demonstrated in 1982 that macrophages from infertile patients with endometriosis phagocytized more sperm than macrophages from infertile patients without endometriosis. The sample size was 32 individuals including 10 patients who had endometriosis. To our knowledge, this result has not been duplicated. However, the phagocytosis assay was different from the current investigation in that the concentration of macrophages and the total number of sperm used were different. The hypothesis that increased phagocytosis of sperm may account for infertility associated with endometriosis is an attractive one. This is particularly so since there is evidence that macrophages are present within the fallopian tubes and it is hypothesized that these may be of peritoneal origin.[12] However, Stone and Himsl[13] recently demonstrated in laparoscopies performed 2-4 hours after insemination that sperm recovery from the cul-de-sac was not significantly different between infertile patients with and without endometriosis. Since neither an increased concentration of macrophages nor increased sperm phagocytosis by existing macrophages was encountered in this investigation, no evidence was found to support the hypothesis that increased sperm phagocytosis is causative in infertility associated with endometriosis.

Macrophages are highly metabolic cells. Their secretory products include prostaglandins, thromboxanes, hydrolytic enzymes, and lymphokines. Recently much interest has focused on peritoneal fluid concentrations of prostaglandins and leukotrienes in infertile patients with endometriosis. These compounds may alter tubal motility and thus impair fertility. Drake et al.[5] demonstrated increased levels of thromboxane B_2 and 6-keto-prostaglandin $F_{1\alpha}$ in patients with endometriosis. DeLeon et al.[10] demonstrated higher concentrations of prostaglandin $F_{2\alpha}$, prostaglandin E_2, thromboxane B_2, and 6-keto-prostaglandin $F_{1\alpha}$ in patients with endometriosis. However, the data are not completely clear. Rock et al.,[9] restricting their analysis to the late proliferative phase, found no difference in concentrations of prostaglandin E_2, prostaglandin $F_{2\alpha}$, and thromboxane B_2 in patients with and without endometriosis. In this investigation, a new secretory product of macrophages, interleukin 1, was measured. Macrophages are involved in two ways in antigen-specific T-cell recognition. They must bind and present antigens to the T cells. Also macrophages produce a peptide known as interleukin 1 with a molecular weight of approximately 15,000 daltons. Interleukin 1 induces T-cell production and release of interleukin 2, which causes proliferation of T cells.[14] To our knowledge, no previous study has quantitated peritoneal fluid levels of interleukin 1 or peritoneal macrophage production rates of interleukin 1 in patients with and without endometriosis. In this investigation, no differences in these two parameters were found when patients with and without endometriosis were compared. Recently, Cannon and Dinarello[15] reported increased serum levels of interleukin 1 in the luteal phase. It is of interest that no variation of interleukin 1 activity within peritoneal fluid was found during the menstrual cycle. However, it should be noted that our samples were cross sectional and perhaps obscured individual cycle variations.

Because of the various aberrations in peritoneal fluid that have been reported, there is concern that peritoneal fluid from patients with endometriosis may be toxic to gametes or early embryos. Morcos et al.,[16] using a two-cell mouse embryo system, reported a significant lowering of the rate of development to the blastocyst stage when mouse embryos were incubated in a solution of 5% peritoneal fluid (heat inactivated). However, the sample size was small (n = 28). In the current investigation with a sample of 64 peritoneal fluid specimens, we could not demonstrate a difference in the rate of development to the blastocyst stage in patients with and without endometriosis. Also no difference was found between the peritoneal fluid groups and the control group. Of note is the fact that we did not heat inactivate the peritoneal fluid. To document further whether macrophages produce substances that are embryotoxic, the growth of two-cell mouse embryos was studied in solutions containing supernatant from macrophage cultures. Since lipopolysaccharide is known to stimulate macrophage production of interleukin 1 and prostaglandins, macrophages were also stimulated with lipopolysaccharide and suppressed with indomethacin. No statistically significant differences either between experimental groups or between each group and the control group were demonstrated. These results suggest then, in the early mouse embryo model, that peritoneal fluid from patients with endometriosis is nontoxic. Also peritoneal macrophages do not appear to produce in vitro metabolites or products that are toxic to the early mouse embryo.

In this investigation, with a sample size of 122 individuals, a significant difference in peritoneal fluid volume, in concentration of macrophages, or in total con-

tent of pelvic macrophages could not be demonstrated. No significant difference in macrophage-mediated sperm phagocytosis in vitro was found. Interleukin 1 levels in peritoneal fluid and the production rate in vitro were similar for patients with and without endometriosis. Peritoneal fluid from patients with endometriosis did not appear to impede the two-cell mouse embryo from development to blastocyst. Peritoneal macrophages from patients with endometriosis did not appear to produce embryotoxic substances.

The search for an etiologic connection between endometriosis and infertility has been a complex one. Conflicting data appear to be developing more rapidly than consensus information. Small sample size is a significant problem in this literature. Also cycle analysis is quite significant in some parameters, for example, peritoneal fluid volume. The selection of adequate control groups is also problematic; some investigators use infertile patients without endometriosis as controls while others choose fertile individuals who are to undergo sterilization. Bioassays are also typically quite variable and require painstaking controls in order to yield meaningful results. Also individuals with endometriosis may not form a homogeneous population. This may be due at least in part to the extent of the disease. Within the context of this investigation, we could not definitively demonstrate an abnormality in the local peritoneal environment that could account for the infertile state associated with endometriosis.

We are grateful to Dr. Susan O'Dorisio for her help in designing the experimental protocol. We wish to express our thanks to Catherine Franke and Frederick Miller for laboratory assistance in implementing portions of the experimental protocol.

The morphologic effect of short-term medical therapy of endometriosis

Ivo A. Brosens, M.D., Ph.D., Ann Verleyen, M.D., and Freddy Cornillie, D.Sc.
Leuven, Belgium

A clinicopathologic study of a short-term medical treatment of endometriosis with danazol or gestrinone was performed in 50 patients with endometriosis and infertility. The cellular response to the therapy was evaluated and graded according to morphologic, that is, histologic and ultrastructural, criteria. A 2-month therapy with 1.25 mg of gestrinone daily induced a degree of cellular inactivation and degeneration of the endometriotic implants that was more pronounced than after 4 months of therapy with either gestrinone (2.5 mg twice or thrice weekly) or danazol (600 mg daily). There was no correlation between the morphologic response to treatment and either the hormonal response of the foci during the menstrual cycle before therapy or the change in laparoscopic staging of endometriosis at the end of therapy. It is suggested that a short-term medical treatment should be further evaluated clinically in the treatment of endometriosis and infertility. (Am J Obstet Gynecol 1987;157:1215-21.)

Key words: Endometriosis, danazol, gestrinone

Clinical studies of the treatment of endometriosis in infertility are faced with major difficulties in evaluating the effects of treatment. The ultimate parameter in infertility is pregnancy. However, the relationship between endometriosis and infertility is complex and many unrelated factors may interfere with the outcome. Large, prospective and controlled clinical studies are difficult to perform. Laparoscopy has been used to evaluate the effect of medical treatment and a variable degree of resolution has been described after long-term therapy.[1] Recent ultrastructural studies have detailed the cellular changes in the endometriotic implants during suppressive hormonal therapy with either danazol[2, 3] or gestrinone.[4, 5] Long-term therapy with danazol results in cellular inactivity and a variable degree of cellular disintegration but not in disappearance of the implant[2] and is associated with multiple side effects and metabolic changes. In view of these considerations a clinicopathologic study was performed to compare the morphologic effects of a 4-month versus a 2-month regimen of medical therapy of endometriosis in patients with infertility.

Material and methods

Clinical data. Fifty patients with endometriosis and infertility were admitted to the study. The clinical diagnosis of endometriosis was confirmed by laparoscopy in all patients and one or more biopsies were performed in suspected foci endometriosis. After the clinical diagnosis the patients were treated with either danazol or gestrinone for periods of 4 or 2 months (Table I). At the end of therapy laparoscopy was performed and the degree of endometriosis was assessed according to the revised American Fertility Society classification system.[6] Small biopsy specimens were taken from the suspected endometriotic foci with a 3 mm punch biopsy forceps (Wolf Endoskope, Knittlingen, West Germany). Ovarian and/or peritoneal biopsies were performed in 18 patients before and after therapy, in seven patients before therapy only, and in 25 patients after therapy only.

Table I. Schemes of medical therapy and number of patients

Product	*Dose*	*Duration of therapy (months)*	*No. of patients*
Danazol	600 mg daily	4	12
Gestrinone	2.5 mg twice or thrice weekly	4	20
	1.25 mg daily	2	18

Morphologic techniques. Tissues were immediately immersed in cold (4° C) 0.1 mol/L phosphate-buffered (pH 7.2) 1.25% glutaraldehyde. After this primary immersion they were cut into small blocks, their size not exceeding 2 mm^3. In total, 360 tissue blocks were sampled (74 tissue blocks of material obtained before treatment and 286 tissue blocks after treatment) and further processed for histologic and transmission electron microscopic examination as described previously.[4] Semi-

thin (1 μm) sections were cut with a Sorvall Porter Blum MT2 ultramicrotome (Du Pont Company, New York, New York) by use of glass knives. From each tissue block several semithin sections were mounted and stained with toluidine blue according to the method of Humphrey and Pittman.[7] They were screened for the presence of endometriotic lesions including endometrial surface and/or glandular epithelium to confirm a histologic diagnosis of endometriosis.

From 39 patients 95 tissue blocks bearing endometriotic foci were studied by transmission electron microscopy. Thin sections (50 to 70 nm) were cut with an LKB ultramicrotome (LKB Instruments, Sweden) by use of a diamond knife. They were stained with uranyl acetate and lead citrate[8] and examined with a Zeiss 9 electron microscope (Zeiss).

The morphologic changes of the endometriotic foci during the menstrual cycle were graded as follows: Grade 0 = undifferentiated endometriotic epithelium and stroma without proliferative and/or secretory changes (no response); grade 1 = weak response with only scanty proliferative and/or secretory transformation within part of the epithelium and stroma; grade 2 = good response with clear proliferation and/or secretion in many endometriotic cells. This morphologic staging according to the differentiation of the endometriotic foci was done for all pretreatment biopsy specimens that were not timed with respect to ovula-

Fig. 2. Weak therapy response. These endometriotic epithelial cells from the uterosacral ligament reveal an undifferentiated aspect lacking proliferative and secretory transformations. Biopsy performed after 4 months of gestrinone therapy (2.5 mg twice weekly). (Original magnification ×5400.)

tion. Thus, the aim of this staging was to evaluate the endocrine dependency of the implants during the cycle. It was shown earlier that endometriotic implants usually reveal less cellular differentiation than eutopic endometrium, while some implants may show no differentiation at all.[9] Furthermore, differentiation of endometriotic foci may be out of phase with that found in the endometrium. According to Schweppe and Wynn,[9] this staging of the differentiation of endometriotic implants should correlate with the degree of therapeutic response, that is, well-differentiated foci (type 2 hormonal response during the cycle) should reveal good response to medical therapy (grade 2 morphologic changes; see below).

The morphologic changes during therapy as described by Cornillie et al.[4] were graded as follows: grade 0 = no response with focal proliferative and/or secretory changes still present (Fig. 1, *A* and *B*); grade 1 = weak response; the endometriotic foci are undifferentiated but lacking clear involutionary changes (Fig. 2); grade 2 = good response with marked cellular involution and degradation (Fig. 3, *A* and *B*). All biopsy specimens were evaluated by one of the authors (F. C.) in the absence of knowledge of clinical data.

Results

Before therapy. The diagnosis of endometriosis was confirmed morphologically in 84% of the biopsies performed before treatment. The scoring of the hormonal response during the menstrual cycle is given in Table II. The hormonal response was absent in 42% of all biopsy specimens, weak in 35%, and good in 23%.

Therapeutic response. The diagnosis of endometriosis was confirmed in 68% and 78% of the biopsy specimens taken after 4 and 2 months of therapy, respectively (Tables III and IV). The scoring of the therapeutic response according to the site of biopsy is given in Tables III and IV. During both regimens of therapy good response was seen more frequently in peritoneal

than in ovarian biopsy specimens. There was a lack of response during the 4-month therapy in both peritoneal and ovarian biopsy specimens and during the 2-month therapy in ovarian biopsy specimens only. Also the therapeutic response to gestrinone therapy was more pronounced in peritoneal biopsy specimens after a 2-month therapy with 1.25 mg daily than after a 4-month therapy with either 600 mg of danazol daily or 2.5 mg of gestrinone twice or thrice weekly (Table V). No significant difference in the grading of morphologic response was found between the 4-month treatment with 2.5 mg of gestrinone twice or thrice weekly and 600 mg of danazol daily.

No correlation could be demonstrated between the

morphologic response to therapy and the scoring of the response during the menstrual cycle before therapy (Fig. 4). The change in the laparoscopic staging of endometriosis according to the revised American Fertility Society classification system at the end of therapy also did not correspond with the morphologic response to therapy (Table VI).

Comment

Both danazol[2, 3] and gestrinone[4, 5] therapies may induce cellular inactivity and degeneration. This type of cellular involution is substantiated by increased numbers of lysosomes and autophagic vacuoles as well as nuclear changes including deep indentations of the nuclear membrane, condensation of the chromatin, and pyknosis. Endometriotic epithelial cells revealing this type of cytoplasmic and nuclear involution become necrotic and are shed from the basement membrane. Thus this type of involution results in a decreased cell number. Sometimes, however, only a minority of epithelial cells show the nuclear degenerative changes, while cytoplasmic disintegration due to enhanced lysosomal activity is the most common finding for grade 2 therapy response.

Another type of cellular change during medical therapy is characterized by cytoplasmic lipid overload without other obvious cellular degeneration. This second type of change was seen only after danazol therapy.

At the end of a 4-month therapy the first type of degeneration was seen after either danazol or gestrinone, and the second type only after danazol. Cellular involution with cytoplasmic and nuclear damage may

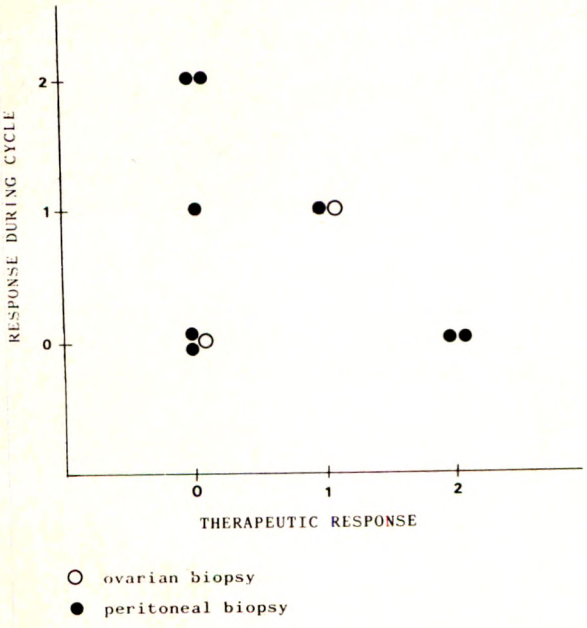

Fig. 4. Correlation between the morphologic response during the menstrual cycle and during therapy in 10 patients with biopsies taken from the same site before and at the end of therapy.

result in cellular death and extrusion of cell remnants into the glandular lumina. Within the cell cytoplasm an enhanced lysosomal activity is seen, while mitochondria, profiles of endoplasmic reticulum, and the perinuclear cisternae usually are dilated and disorganized. Since only this type of involution affects nuclear morphologic features and cytoplasmic organization and finally may result in pyknosis, cellular fragmentation, and extrusion of cell nuclei, it may be concluded that only this first type of cellular degeneration can eliminate individual endometriotic epithelial cells. On the other hand, the presence of large numbers of lipid droplets in ciliated and nonciliated epithelial cells as well as in stromal and perivascular cells induces no dramatic nuclear damage; therefore, this cellular change probably cannot be regarded as lethal.

The present comparative study indicates that a 2-month therapy with gestrinone (1.25 mg daily) can induce a degree of cellular inactivation and regression in peritoneal endometriotic implants that is more pronounced than after a 4-month therapy with either gestrinone (2.5 mg twice or thrice weekly) or danazol (600 mg daily). Furthermore, our morphologic findings are in agreement with the clinical observation that ovarian implants of endometriosis are more resistant to medical therapy than are peritoneal implants but do not support the hypothesis that prolonged medical therapy with either danazol or gestrinone can eradicate endometriotic implants. Cellular involution and degradation are seen in approximately 25% of the implants and this effect is apparently not increased with prolongation of the treatment. On the contrary, if the dose is increased, a 2-month therapy with gestrinone can produce a stronger effect on the implant than can a 4-month therapy.

The advantages of a short-term medical therapy of endometriosis in infertility patients are obvious but the clinical value needs further investigation. On the other hand, the rationale for long-term medical therapy of endometriosis in infertility has never been clear. Although long-term therapy is frequently required for the treatment of pelvic pain in endometriosis there are no reasons to assume that the mechanisms of pain and infertility in endometriosis are related to each other. A beneficial effect of pregnancy on endometriosis has been proposed as a model for hormonal therapy and a long-term estrogen-progestogen therapy was introduced by Kistner.[10] However, the beneficial effect of pregnancy on endometriosis has been questioned and the remarkable involutionary processes during the postpartum period are as likely to cause regression of endometriosis as is the hormonal status of a 9-month gestation. Laparoscopic observation has shown regression and involution of endometriotic implants after long-term medical therapy. However, laparoscopic evaluation of endometriosis can be misleading in the evaluation of the effect on the implants in terms of tissue. Laparoscopy reveals the sequelae of endometriotic activity such as secretion, hemorrhage, inflammatory reaction, or complications such as adhesions and endometrioma formation but not the implant itself.[11] When laparoscopic evaluation of the therapeutic effects is performed at the end of or immediately after therapy, the ovarian function is still suppressed and the effect of treatment is compared under two different hormonal conditions. Inactivation of the endometriotic implant may allow regression of the secretory activity, hemorrhage, and inflammatory reaction. However, regression and resorption of the implant in terms of cells can be verified only by morphologic examination of the suspected focus. If laparoscopy is used as the method for evaluation of the therapeutic effect, it should be planned by preference not at the end of therapy but during one of the cycles after treatment, when the ovarian function has been restored.

Cord sampling for the evaluation of oxygenation and acid-base balance in growth-retarded human fetuses

Giorgio Pardi, M.D., Mauro Buscaglia, M.D., Enrico Ferrazzi, M.D., Patrizia Bozzetti, M.D., Anna Maria Marconi, M.D., Irene Cetin, M.D., Frederick C. Battaglia, M.D., and Edgar L. Makowski, M.D.

Milan, Italy, and Denver, Colorado

In 14 pregnancies complicated by intrauterine growth retardation, the umbilical cord was sampled before delivery under ultrasonic guidance for rapid fetal karyotyping. Fetal blood was analyzed for respiratory gases, acid-base balance, and lactate concentrations. Two patients were excluded from the study because cord samples were diluted with amniotic fluid. In six patients (group 1), the clinical assessment warranted continuation of pregnancy. Cesarean sections were performed in the remaining eight patients (group 2) within 8 hours of cord sampling. The data from the two groups were compared with those obtained from umbilical venous blood at the time of elective repeat cesarean section in term appropriate for gestational age infants (controls). No significant difference in Po_2 was found between groups 1 and 2 and controls. In contrast, there were significant differences in oxygen saturation and acid-base balance between groups 1 and 2. Lactate concentration was inversely correlated with pH and was elevated in five of six fetuses requiring a prompt cesarean section: In two of these five fetuses, nonstress fetal heart rate tracings were reactive. The results suggest that fetal blood biochemistry, and particularly lactate concentration, may represent an additional indicator of fetal well-being in pregnancies complicated by intrauterine growth retardation. (Am J Obstet Gynecol 1987;157:1221-8.)

Key words: Cord blood sampling, lactate concentration, intrauterine growth retardation, respiratory gases, acid-base balance

Recently, techniques have been developed for the sampling of fetal blood from the umbilical cord of human fetuses using the technique of fetoscopy for visualization of the cord. This approach has been extensively used for genetic diagnosis in second-trimester fetuses.[1] More recently, improvements in techniques for ultrasonic visualization of the umbilical cord have permitted direct sampling of fetal blood from third-trimester fetuses from the cord by means of a needle guided by ultrasonography.[2, 3] We were interested in

pursuing the evaluation of fetal blood obtained by this approach in infants with fetal growth retardation. Fetal growth retardation is a fairly common problem in high-risk obstetrics and can be reliably diagnosed. However, no effective therapy in utero is yet available. Clinical management relies on the best timing of delivery to avoid severe fetal distress with its attendant neonatal complications. Although the timing of delivery has relied primarily on the interpretation of antepartum fetal heart rate testing and biophysical profile, both have limitations. Thus additional methods are needed to evaluate fetal well-being.

In this study we have performed umbilical cord blood sampling in 14 pregnancies complicated by fetal growth

retardation for rapid karyotyping. The blood samples have also been analyzed for respiratory gases, acid-base balance, and lactate concentrations, and these values were compared with data obtained from umbilical venous blood in 10 normal pregnancies at the time of elective cesarean section.

Material and methods

Patients. Fetal growth retardation was diagnosed in 14 pregnant women by ultrasound measurements of biparietal diameter and cephalic and abdominal circumferences. Gestational age was assessed by the last menstrual period and an ultrasound determination within 20 weeks of pregnancy. Fetal growth retardation was confirmed in all cases after birth by reference to Italian birth weight–gestational age standards.[4] The main indication for fetal blood sampling was rapid fetal karyotyping, since fetal growth retardation is often associated with chromosomal abnormalities.[5] The 14 fetuses reported in this study showed a normal karyotype and no malformations at birth. In 12 of the 14 fetuses, a late flattening of growth was identified whereas two fetuses had a low profile growth curve and marked oligohydramnios. At the time of fetal blood sampling, gestational age ranged from 29 to 38 weeks. Informed consent was obtained from all patients.

In six of the 14 patients, delivery occurred 1 to 3 weeks after cord sampling (group 1). In the other eight patients, a cesarean section was performed within 8 hours of sampling (group 2). Fetal blood biochemical values, even though they were known to the clinical staff, did not primarily influence the timing of delivery. The clinical decision regarding whether the pregnancy should be allowed to continue was based on a multiplicity of factors including the maternal clinical condition, gestational age, antepartum fetal heart rate testing, sonographic evaluation of fetal growth, fetal body and breathing movements, and amniotic fluid volume. In Table I clinical information about the two groups is presented in detail; two samples were judged to be diluted by amniotic fluid (Table II) and were excluded from data analysis.

The control group was made up of 10 patients undergoing an elective cesarean section. All patients had an uneventful pregnancy and the newborns' weights were appropriate for gestational age.[4] At delivery gestational age ranged from 35 to 39 weeks.

In all cases the cesarean section was performed under general anesthesia. Patients were placed in the left lateral recumbent position and received 7 $ml \cdot kg^{-1} \cdot hr^{-1}$ of NaCl 0.9% intravenously. Maternal blood pressure was monitored, and in no instance was hypotensive episodes of greater than 40 mm Hg detected. Immediately after fetal extraction, the cord was doubly clamped, and blood was withdrawn from the umbilical artery and vein.

Technique of umbilical cord blood sampling. The procedure was performed after an overnight fast by means of an aseptic technique: No local anesthetic or intravenous sedative was used. Fetal heart rate testing was recorded before and after the sample.

Fetal blood was sampled from the placental insertion of the umbilical vein by a 20-gauge needle guided by sonography in nine pregnancies according to standard techniques.[2] In four fetuses the sonographic target of the needle was represented by sections of the cord fixed, by the scarcity of amniotic fluid, between fetal parts and the uterine wall. In one fetus a chorionic plate vessel was sampled. In all fetuses the angle between the vessel and the needle was predetermined to approximately 20 to 45 degrees. The sampling procedure never exceeded 10 minutes. Two attempts to insert the needle were necessary in three patients. Sonographic imaging of the site of sampling was obtained by a 5 MHz sector transducer and a pulsed Doppler control of the constant or pulsatile flow of the tip of the needle to verify the venous site of sampling during the procedure. The reliability of fetal sampling was also assessed by com-

parison of maternal and sample hematocrit and hemoglobin concentrations and by analysis of red cell volumes with a Coulter counter. In addition, Kleihauer smears were prepared to confirm the fetal source of blood. After sampling, the cord was continuously visualized by ultrasonography until fetal bleeding ceased. In only one patient cord bleeding persisted more than 60 seconds: After the sample, fetal heart rate underwent a transient mild tachycardia of 170 bpm. In this patients (Table III, No. 7), delivery occurred by cesarean section 2 hours later: Cord hemoglobin concentration decreased from 17.1 to 15.1 gm/dl.

Analytic techniques. Blood for all analyses was collected into heparinized syringes that were immediately sealed and stored on ice; the determinations of lactate concentrations and respiratory gases were carried out within 5 to 10 minutes. Care was taken to treat all blood samples as anaerobically as possible. Hemoglobin concentration and oxygen saturation were determined with a Radiometer OSM-2 oximeter. Oxygen content was calculated from these values by the following equation: Oxygen content (mmol/L) = hemoglobin (gm · L^{-1}) × oxygen saturation × 0.05982. pH, Pco_2, and Po_2 were determined on a Radiometer ABL analyzer. Base deficit was calculated from these data. Lactate concentration was measured with a Yellow Springs analyzer (23L). All biochemical analyses were made in duplicate.

Statistical methods. An unpaired Student *t* test was used to calculate the significance of the difference among groups. Linear regression analyses were carried out by the least squares method.

Results

Reliability of the cord samples. None of the 14 samples was contaminated by maternal blood as confirmed by the Kleihauer smears that showed 100% fetal cells. Two samples, the second and the third in chronologic order of the series, were judged contaminated by amniotic fluid because the hemoglobin concentration was 8.3 and 4.5 gm/dl, respectively, whereas the concentration in umbilical venous blood at delivery was 16.0 and 17.2 gm/dl, respectively. In these two fetuses respiratory gases and acid-base values (Table II) were considered unreliable and excluded from data analysis.

The other 12 cord samples were judged uncontaminated by amniotic fluid by the comparison of hemoglobin concentrations of the cord with delivery samples.

Respiratory gases and acid-base values in cord blood. Biochemical data of the 12 reliable cord samples are reported in Table III together with data obtained from umbilical venous blood at delivery. Fig. 1 presents the Po_2, oxygen saturation, oxygen content, and hemoglobin concentration in the cord blood for the two groups of patients. Similarly, Fig. 2 presents the pH, Pco_2, lactate concentration, and base deficit. In both figures the data are compared with those obtained in the control group. Table IV presents the mean values ± SEM for all the biochemical parameters studied in the three groups.

Lactate versus pH and antepartum fetal heart rate testing. Lactate concentrations and pH values for all umbilical cord blood samples showed a significant negative linear relationship ($p < 0.001$) (Fig. 3). On the contrary, no relationship was found between lactate concentrations and base deficit.

Table V presents a comparison of lactate concentrations with nonstress fetal heart rate testing recorded within an hour after the procedure was completed. For lactate concentrations higher than 1.5 mmol/L (five of six patients in group 2), fetal heart rate was reactive in two fetuses.

Comment

The introduction of cord blood sampling under ultrasound guidance during the third trimester presents the obstetrician with an unique opportunity to evaluate the fetus biochemically in a relatively undisturbed condition. It is conceivable that the addition of such information in conjunction with antepartum fetal monitoring may increase the precision with which fetal well-being can be determined. The technique of cord blood sampling required the facilities of a perinatal intensive care center together with a skilled perinatology team, including an expert ultrasonographer. Although this technique is invasive, we have not noticed any serious maternal or fetal complication thus far. This includes 22 other patients in whom the procedure was performed for indications other than fetal growth retardation. The safety of cord sampling has also been reported in two previous papers.[2, 3]

A prime requisite for proper interpretation of the sample is that it be fetal blood uncontaminated by maternal blood or amniotic fluid. In the present study, contamination with maternal blood never occurred. Unfortunately, the Coulter counter cannot be used to differentiate fetal from maternal blood during the last 10 weeks of gestation as it can at 20 weeks, since the difference between fetal and maternal red cells volume is much less. However, the Kleihauer smear is able to discriminate fetal from maternal blood, although the

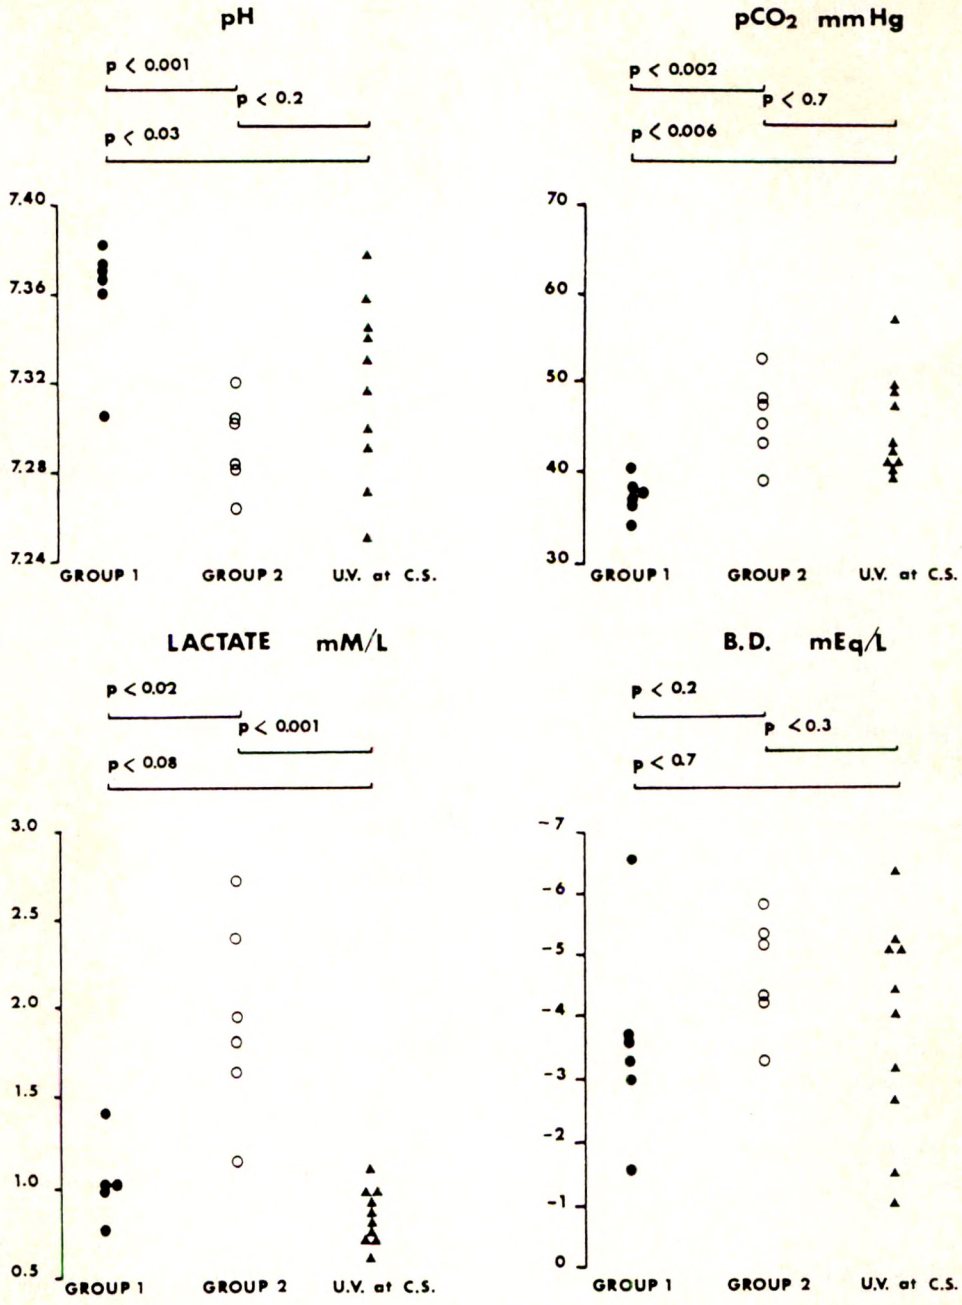

Fig. 2. Comparisons of pH, P_{CO_2}, lactate concentration, and base deficit between groups 1 (●) and 2 (○) and between the two groups and the control group (▲). (*U. V.* = Umbilical venous; *C. S.* = cesarean section.)

results are not immediately available. Futher methods for rapidly discriminating fetal from maternal blood would be helpful.

A second more vexing problem is that of dilution with amniotic fluid, which must be rapidly identified if the biochemical data are to be used for clinical decisions. Since the pH of amniotic fluid is approximately 7.1 and lactate concentration is much higher than that of fetal blood,[6] contamination by amniotic fluid would decrease blood pH and increase lactate concentration. Such contamination could mistakenly suggest fetal distress. Hemoglobin concentration is also decreased by dilution with amniotic fluid and can provide a crude guide when dilution is fairly marked, but better markers of amniotic fluid contamination need to be developed.

In this study the primary indication for cord blood sampling was rapid fetal karyotyping in growth-retarded fetuses, as well as for the evaluation of fetal oxygenation and acid-base balance. In group 1 (six patients), pregnancy was allowed to continue, whereas in group 2 (six patients), the fetuses were judged to be in jeopardy and an immediate cesarean section was per-

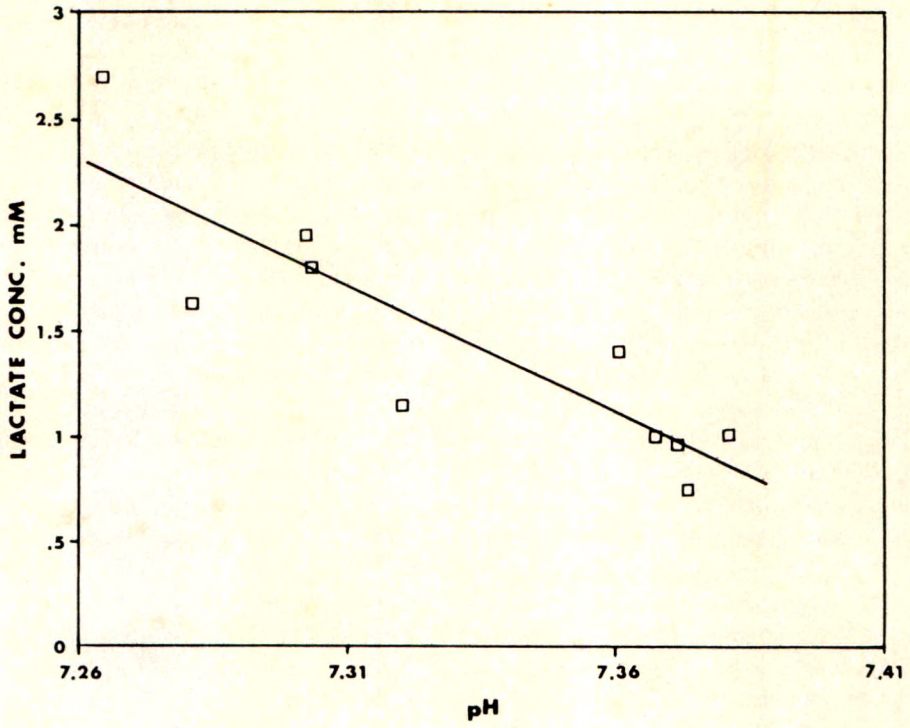

Fig. 3. Lactate concentration versus pH in the cord samples (□ cord samples): $y = 90.3 - 12.1\ x$; $r = 0.88$; $p < 0.0009$.

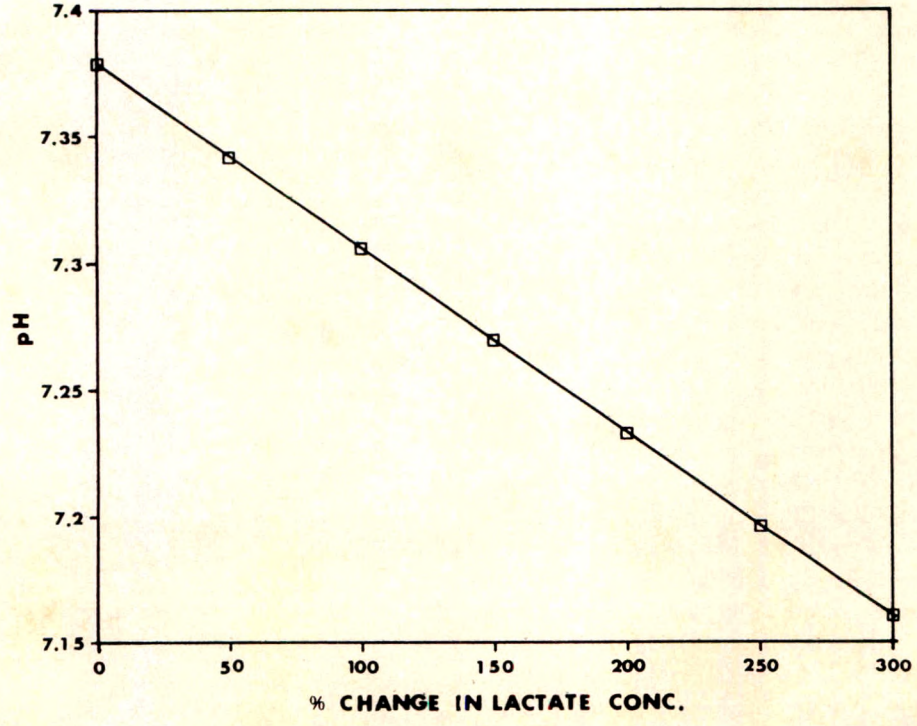

Fig. 4. Cord pH versus percentage change in lactate concentration.

formed. For obvious ethical reasons, normal controls are not available. Thus, we used as a reference the biochemical data obtained from sampling the umbilical cord of normal term fetuses at the time of elective repeat cesarean section, even though the stress of anesthesia and surgery might have affected these values in the sense of a mild acidosis.

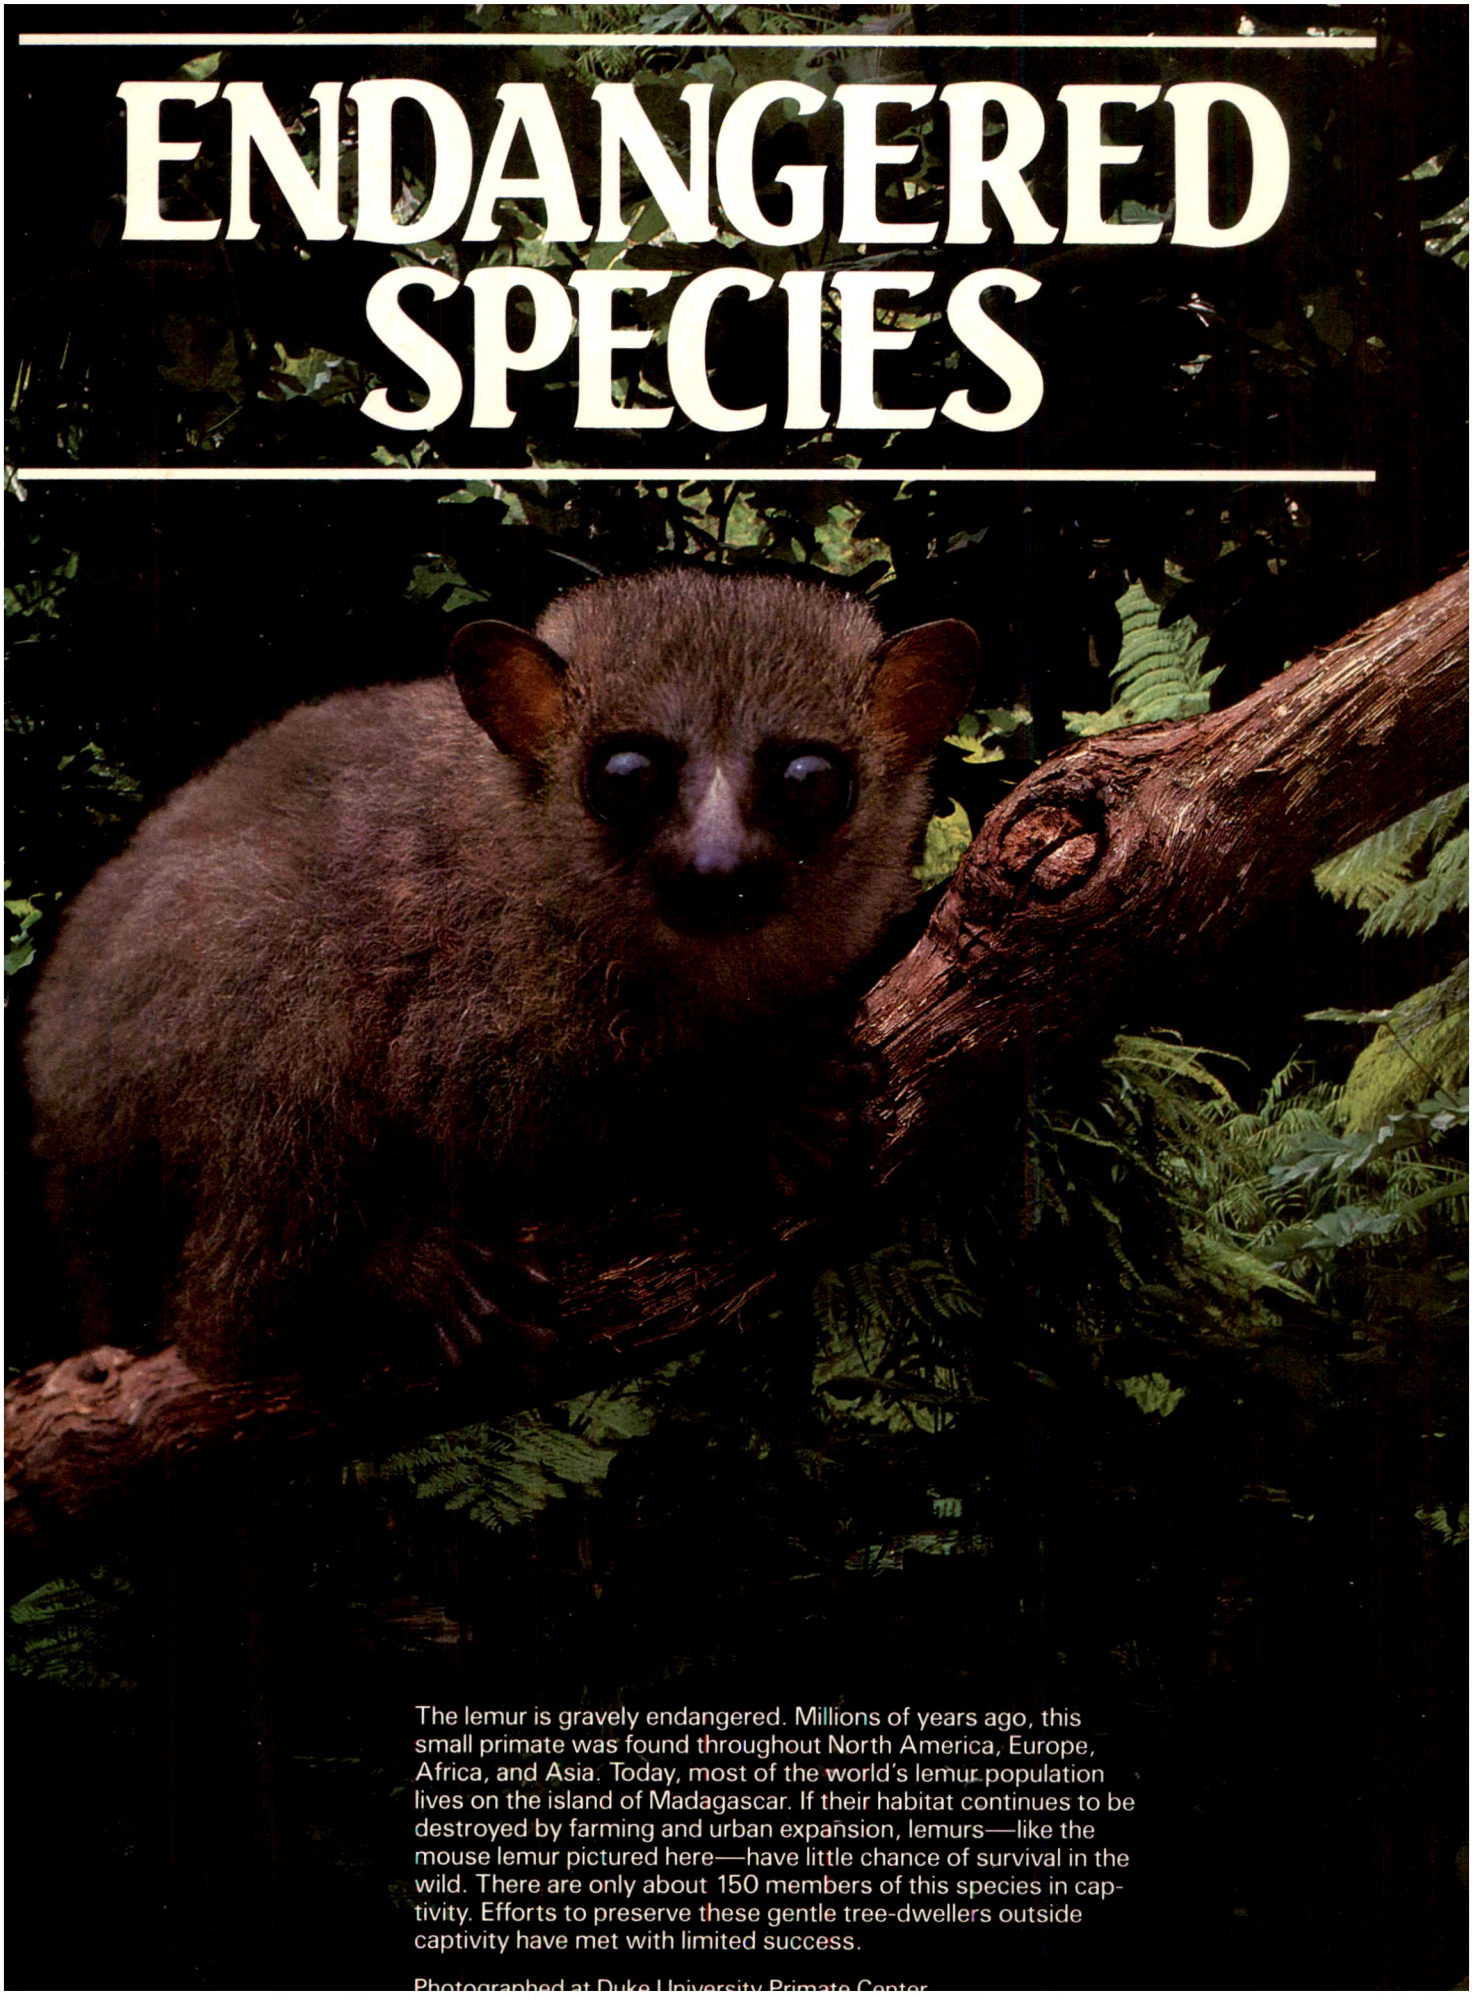
An important observation in this study is that the

biochemical parameters in group 1 patients were essentially the same as those in the control group with the exception of a lower P_{CO_2} and a higher pH. On the contrary, major differences were detected between the two groups of growth-retarded fetuses. Despite similar P_{O_2} values, oxygen saturation was decreased in group 2 patients, which presumably reflects lower pH values and the attendant shift in the hemoglobin dissociation curve. The increase in hemoglobin concentrations in group 2 compared with both group 1 and controls explains the lack of difference in oxygen content.

The fact that P_{O_2}, as previously mentioned, was not different in group 2 compared with both group 1 patients and control is rather striking. We believe that this may reflect the fact that umbilical venous blood and not arterial blood was sampled, which suggests that a major problem for the exchange of respiratory gases in small for gestational age infants may be a reduction in umbilical blood flow rather than a reduction in placental-diffusing capacity. Such a hypothesis is consistent with the data obtained by Griffin et al.,[7] who demonstrated an increase in placental resistance in human growth-retarded fetuses that would induce a reduction of umbilical blood flow.

It should be emphasized that the range of P_{O_2} values shown in Fig. 1 for patients in group 2 is very large and not uniformly distributed. As more data accumulate from various medical centers, the identification of a subgroup with lower P_{O_2} values may be feasible. Certainly, one would expect to see a decrease in umbilical venous P_{O_2} in those high-risk pregnancies complicated by a reduction in uterine blood flow, a phenomenon clearly demonstrated in the studies of Wilkening and Meschia[8] in pregnant sheep.

In contrast to the oxygen data, the acid-base data were less equivocal in discriminating group 1 and 2 patients. As shown in Fig. 2, pH was significantly lower and lactate concentration was significantly higher in fetuses delivered by immediate cesarean section compared with the other groups. In our experience a pH lower than 7.30 and a lactate concentration higher than 1.5 mmol/L should be considered bad prognostic indicators. As shown in Fig. 3, fetal blood lactate concentration is inversely related to blood pH. With use of the regression analysis depicted in Fig. 3, Fig. 4 was then constructed to illustrate that changes in lactate concentration may be more sensitive indicators of fetal distress than changes in pH. The mean lactate concentration found in normal patients undergoing elective cesarean section (0.84 mmol/L) was taken as 0% change. Fig. 4 clearly illustrates that an increase in lactate concentration of 100% would still be associated with a pH >7.30.



It has been shown in animal species that the normal fetus consumes lactate that is produced by the placenta.[9, 10] Placental production of lactate has also been demonstrated in humans.[11] Under acute hypoxic conditions, the fetus may become a net producer of lactate and fetal blood lactate concentration increases.

It is important to stress that the lactate values presented in this article were obtained with a methodology that permitted completion of the analyses within 5 minutes of sampling. Lactate concentration was always measured first on all samples. It is also important to stress the fact that high lactate concentrations were present in fetuses with normal antepartum fetal heart rate tracings. This might indicate that lactate concentration may represent an earlier indicator of a change in fetal well-being. Certainly, the question of whether fetal blood biochemical analyses would aid in the recognition of fetal distress deserves further confirmation as the technique of cord sampling is more widely used in obstetrics.

ENDANGERED SPECIES

The lemur is gravely endangered. Millions of years ago, this small primate was found throughout North America, Europe, Africa, and Asia. Today, most of the world's lemur population lives on the island of Madagascar. If their habitat continues to be destroyed by farming and urban expansion, lemurs—like the mouse lemur pictured here—have little chance of survival in the wild. There are only about 150 members of this species in captivity. Efforts to preserve these gentle tree-dwellers outside captivity have met with limited success.

Photographed at Duke University Primate Center

ENDANGERED SPECIES?

Is the practice of obstetrics endangered? Its survival is threatened by factors that have the potential to diminish significantly the number of practicing obstetricians. The continuing increase in the number of malpractice lawsuits against physicians and the corresponding inflation of liability insurance premiums have plunged the obstetrics specialty into a crisis.

Patient-initiated litigation is now so common that 1 in 6 obstetrician/gynecologists is sued each year, compared with 1 in 20 only ten years ago. As a result, obstetricians pay three to four times more for malpractice insurance than do physicians in most other specialties.

Survival of the practice of obstetrics is further jeopardized because fewer students are entering the specialty and the number of experienced physicians leaving obstetrics or retiring early is on the rise. For many physicians, the crisis has taken the joy out of practicing medicine.

AVOIDING THE DANGER OF EXTINCTION

Immediate action is necessary in order to preserve the practice of obstetrics. In response to this need, G.D. Searle & Co. has organized the Searle Alliance for Health Care. Its purpose is to help lead a national effort to resolve the medical professional liability crisis.

Components of a campaign developed by the Alliance include: nationwide teleconferences and audioconferences; strategy to petition legislators for reform; educational programs and seminars; and national advertising to raise public consciousness of the crisis.

Operating on a national and personal level, the Searle Alliance for Health Care can provide information to help you in your practice. Learn more about medical professional liability and how we can provide information about the problem of professional liability. Contact your Searle representative for more information on the Searle Alliance for Health Care.

Demulen 1/35™
(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

© 1987, Searle & Co.

Demulen 1/35™

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Demulen 1/35™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 35 mcg. Each blue tablet in Demulen 1/35-28 is a placebo containing inert ingredients.

Demulen 1/50™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 50 mcg. Each pink tablet in Demulen 1/50-28 is a placebo containing inert ingredients. **Indication and usage:** For prevention of pregnancy. Pregnancy rate for products with ≥35 mcg ethinyl estradiol or ≥50 mcg mestranol is ≤1/100 woman-years. With ≤35 mcg ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. *Dose-related Thromboembolic Risk:* Studies showed positive association between OC estrogen dose and thromboembolic risk. It is in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new users on ≤50 mcg estrogen. **Contraindications:** Thrombophlebitis, thromboembolic disorders, past history of deep vein thrombophlebitis or thromboembolic disorders; cerebrovascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal genital bleeding; past or present, benign or malignant liver tumors developing during use of estrogenic products. **Warnings:**

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke. OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

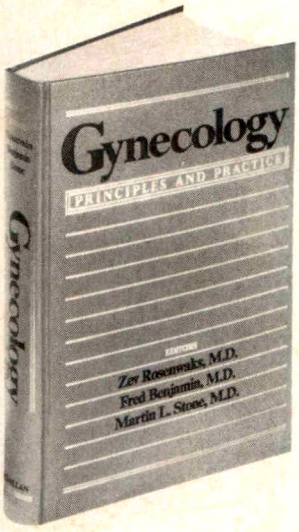
1. *Thromboembolic disorders and other vascular problems:* Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased risk for fatal venous thromboembolism (TE). British and U.S. studies showed increased risk for nonfatal disease. U.S. studies showed increased risk for stroke. OC users were 2-11 times more likely to manifest these diseases without evident cause. In a study of idiopathic deep vein thrombosis and pulmonary embolism (PE), projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. Overall excess mortality from PE or stroke was 1.3-3.4 deaths/year/100,000 users and increased with age. *Cerebrovascular Disorders:* In a study of stroke with and without predispositions, risk of hemorrhagic stroke was 2 times greater and thrombotic stroke 4.0-9.5 times greater in users. Mortality trends in 21 countries indicate that changes in cardiovascular mortality were associated with changes in OC prevalence. The Royal College of GPs (RCGP) reported on its prospective study: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." A 1981 analysis showed a 4-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age and smoking. A 1983 analysis showed elevated cerebrovascular disease, increasing with use to 8 yrs, including cerebral thrombosis or embolism and TIA. Peripheral arterial disease and MI were increased. Women over 30 had more arterial disease, being greatest in smokers. Arterial case-fatality was 2-3 times greater for users who smoked. Family Planning Assoc. (FPA) found significant association between OC use and stroke; increased risk for venous thrombosis and PE was 4-fold and statistically significant. Mortality from nonrheumatic heart disease was greater in ever-users. In the Walnut Creek Study, subarachnoid hemorrhage risk was associated with smoking, age, and OC use. *Myocardial Infarction:* Increased risk of MI associated with OCs was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk, regardless of OC use. OCs were an additional risk factor. Excess rate of fatal MI was 3.5/year/100,000 users aged 30-39 and 20 for ages 40-44. (These are based on British statistics with acute MI death rates 2-3 times less than the U.S. Similar estimates for the U.S. are 25.7 for users aged 30-39 with predispositions vs 1.5 without; for ages 40-44, 86.2 vs 5.1.) Excess hospitalization rate for nonfatal MI in Britain was 3.5/year/100,000 users aged 30-39 and 47 for ages 40-44. Smoking major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk than nonsmoking users, but a 10-12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent. U.S. studies similarly relate MI, OCs, smoking, and age.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

	Aged 30-39:	*Users*	*Nonusers*	*Aged 40-44:*	*Users*	*Nonusers*
All smokers		10.2	2.6		62.0	15.9
≥15 cigarettes daily		13.0	5.1		78.7	31.3
<15 cigarettes daily		4.7	0.9		28.6	5.7
Nonsmokers		1.8	1.2		10.7	7.4
Smokers and nonsmokers		5.4	1.9		32.8	11.7

Risk of Dose: Reports of TE after use of OCs with ≥50 mcg estrogen received by drug safety committees in Britain, Sweden, and Denmark were compared with distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of TE, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg estrogen were associated with higher TE risk than those with 50-80 mcg. Estrogen quantity may not be the sole factor; influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing same estrogen dose nor between ethinyl estradiol and mestranol. In Britain certain TE conditions were associated with progestogen or estrogen dose. In Sweden reports of TE decreased when higher estrogen doses were no longer prescribed. Studies on TE risk with progestogen-only OCs have not been done. Cases have been reported for these; they are not presumed free of risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of TE was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg and those with ≥100 mcg estrogen. For all cases combined, larger doses were associated with only slightly higher risk; for idiopathic cases risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was less increased risk for cases with predispositions. In FPA study no nonhemorrhagic strokes occurred with <50 mcg estrogen, vs 13 with higher doses. TE risk in users and nonusers increases with age. OCs have been considered an independent risk factor. *Persistence of Risk* after OC discontinuation was reported for circulatory disease, nonrheumatic heart disease, and cerebrovascular disease, including subarachnoid hemorrhage, cerebral thrombosis, and TIA. *Excess Mortality from Circulatory Diseases:* A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers by age, smoking, and duration of use. Excess mortality was 23/100,000 users (2 and 10 for ages 25-34, 15 and 48 for ages 35-44, 41 and 179 for ages >44, for nonsmokers and smokers, respectively). Risk was significant only for smokers over 34. Most deaths were due to subarachnoid hemorrhage or ischemic heart disease. Risk for ever-users rose with parity. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (eg, TE for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers, light smokers about half. Mortality with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with condom or diaphragm backed up by early abortion. Risk of TE and thrombotic disease with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high; B—high; C—moderate; D—low.	Age:	<30	30-39	≥40
Heavy smokers (≥15/day)		C	B	A
Light smokers (<15/day)		D	C	B
Nonsmokers, no predispositions		D	C,D	C
Nonsmokers, with predispositions		C	C,B	B,A



Be alert to earliest manifestations of TE and thrombotic disorders (eg, thrombophlebitis, PE, cerebrovascular insufficiency, coronary artery disease, MI, retinal thrombosis, mesenteric thrombosis). Should any be suspected, discontinue OCs immediately. A 4-7-fold increased risk of postsurgery TE was reported in users; if feasible discontinue OCs at least 4 weeks before surgery or in prolonged immobilization. Before resuming OCs, weigh risks of postsurgery TE complications against contraceptive needs. The RCGP prospective study reported higher incidence of superficial and deep vein thrombosis in users, the former correlated with progestogen dose. The data suggest varicose veins have little effect on development of deep vein thrombosis but substantially increase risk of superficial vein thrombosis, risk depending on severity of varicosities. **2.** *Ocular lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** *Carcinoma:* Long-term estrogen in certain animals increases carcinomas and/or nonmalignant neoplasms, such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. There is evidence that estrogens increase risk of human endometrial carcinoma. In case-controlled studies, increased risk (2.2-13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in areas with cancer-reporting systems, which may be related to rapidly expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics at equi-estrogenic doses. Of the first 30 cases of endometrial carcinoma in OC users under 40, those without predispositions (eg, irregular bleeding before OCs, polycystic ovaries) occurre nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggesting increased endometrial cancer wit combination or progestogen-only OCs, though individual cases were reported. Studies show no increased breast cancer with OCs or estrogen However, greater risk was noted in OC users with benign breast disease or long-term (2-4 years) use. One study found greater risk of brea cancer with >4 years OC use prior to first full-term pregnancy. Risk of breast cancer with menopausal estrogens rose and further increase with duration of follow-up. OCs or estrogen were related to breast cancer in connection with other risk factors. Decrease in benign brea tumors in OC users is well known. Some studies suggested increased risk of cervical dysplasia, erosion, and carcinoma in long-term user Cervical microglandular hyperplasia has been reported. In summary, there is no consistent evidence from human studies of increased canc risk with OCs. Close surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vaginal bleeding, consid nonfunctional causes and take diagnostic measures to rule out malignancy. Carefully monitor users with strong family history of breast canc or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnormal mammograms, or cervical dysplasia. **4.** *Hepatic adenomas, et* have been associated with OCs. In 1 study OC formulations with high "hormonal potency" were associated with higher risk, as was age ov 30. Though benign, these lesions may rupture and cause fatal hemoperitoneum in short- or long-term users. Two studies related risk t duration of use, being much greater after ≥4 years. Long-term OC users have an estimated adenoma incidence of 3-4/year/100,00 Consider such lesions in users with abdominal pain, tenderness, mass, or shock. About 25% present with abdominal masses, up to half wi acute hemoperitoneum. Radiologic and lab studies may not be helpful; liver scans may show local defect. Hepatic arteriography or CAT ma be useful. Hepatocellular carcinoma risk is increased 7-20 times in users for 8 or more years. OCs are contraindicated in case of past present, benign or malignant liver tumors developing during use of estrogenic products. **5.** *Use in or immediately preceding pregnancy; bir defects, malignancy in offspring:* Estrogens or progestogens during early pregnancy may seriously damage offspring. Females exposed in ute to DES and other nonsteroidal estrogens may have increased risk of vaginal or cervical cancer. Though OCs may not enhance this risk, monit such patients carefully. From 30-90% of DES-exposed women develop benign vaginal or cervical adenosis, which could be premalignant. DE exposed daughters have more unfavorable pregnancy outcomes. Males so exposed may develop urogenital and sperm defects. Other estroge may mimic DES. Reports relate fetal exposure to female sex hormones and congenital anomalies, eg, VACTERL for vertebral, anal, cardia tracheoesophageal, renal, and limb defects. There appears preferential expression by males. There was a 4-7-fold increased risk of lim reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal pregnancy tests, or treatment for threaten abortion). Some exposures were very short, being only a few days. Cardiovascular defects in children exposed to female hormones, includi OCs, during early pregnancy occurred in 18.2/1,000 births, compared to 7.8 for those unexposed (P<.05). More twinning was reported conceptions shortly after OC discontinuance. Female sex hormones were used for threatened or habitual abortion, but there is considerat evidence estrogens are ineffective and no evidence progestogens are effective. Triploidy and possibly other polyploidy may be increased abortuses from women becoming pregnant soon post-OC. These almost always abort spontaneously. It is unknown if spontaneous abortion increased soon after stopping OCs. Increased chromosome aberrations have been reported. Safety of OCs in pregnancy has not be demonstrated. Rule out pregnancy in using OCs and always consider it if withdrawal bleeding does not occur. If 2 consecutive periods a missed rule out pregnancy before continuing. If user deviates from regimen, consider pregnancy at first missed period and withhold OCs. pregnancy is confirmed, apprise patient of potential fetal risks and discuss continuation of pregnancy. Users discontinuing for pregnancy shou use alternative contraception for 3 months before attempting to conceive, though this is not based on precise information. Do not u progestogen-only or progestogen-estrogen drugs as pregnancy tests. **6.** *Gallbladder disease* risk, surgically confirmed, appeared after 2 year use and doubled after 4-5 years in 1 study; it appeared in 6-12 months' use in another. **7.** *Carbohydrate and lipid metabolism:* Decreasi glucose tolerance occurs in a significant number of users; carefully observe diabetic and prediabetic patients. Triglycerides and tot phospholipids may increase. **8.** *Elevated blood pressure* (BP) occurs in some users in a few months, and degree may relate to progestog dose. Hypertension prevalence in users is not higher in the first year, but increases with longer exposure; in the 5th year it is 2½—3 tim the first year. Age is strongly correlated with hypertension in users. Those with history of elevated BP (hypertension), preexisting ren disease, history of toxemia or elevated BP in pregnancy, familial tendency to hypertension or its consequences, or history of excessive weig gain or fluid retention during menstrual cycles may be more likely to develop elevated BP on OCs and should be monitored closely. Ev though elevated BP may be in "normal" range, do not ignore implications. Follow closely, particularly those with other risk factors cardiovascular disease or stroke. High BP may or may not persist after stopping OCs. **9.** *Headache:* Onset or exacerbation of migraine development of headache of a new pattern that is recurrent, persistent, or severe requires stopping OCs and evaluating cause. **10.** *Bleed irregularities:* Breakthrough bleeding (BTB); spotting, and amenorrhea are frequent reasons for discontinuing. In BTB, as in all cases of irregu bleeding, consider nonfunctional causes. In undiagnosed persistent or recurrent bleeding, rule out pregnancy or malignancy. If pathology excluded, time or change to another product may suffice. Change to a higher-estrogen OC only when necessary as this may increa thromboembolic risk. Those with history of oligomenorrhea or secondary amenorrhea or without established regular cycles may be anovulat or amenorrheic after discontinuing. Those with such problems should be so informed and other methods encouraged. Post-use anovulatic possibly prolonged, may occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitary tumors has be associated with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolactin-secreting tumors in patients w postpill amenorrhea when galactorrhea was present. **11.** *Ectopics:* In failures with combination OCs, the ratio of ectopic to intrauteri pregnancies is no higher than in nonusers. There may be increased risk of ectopics after discontinuing. **12.** *Breast feeding:* OCs may decrea quantity and quality of milk. A small fraction of OC steroids appears in milk. Effects if any on child are unknown. If feasible defer OCs ur after weaning. **13.** *Infertility* may occur after discontinuing OCs. While impairment diminishes with time, there is still an appreciable differen in nulliparas aged 25-29 after 30 months; difference is negligible after 48 months. In nullips aged 30-34 impairment persists to 72 mont and is more severe for 2-year users. In paras aged 25-34, difference is negligible after 30 months. **Precautions:** Conduct complete histo and physical prior to OC use and annually thereafter. Include breasts, abdomen, and pelvis, with BP, Pap, and lab tests. Preexisting uteri leiomyomata may enlarge. Mental depression may occur; with positive history, observe carefully and discontinue if serious recurrence. Flu retention may occur; prescribe cautiously and monitor carefully in convulsive disorders, migraine, asthma, or cardiac, hepatic, or ren dysfunction. History of jaundice in pregnancy increases risk of recurrence on OCs; observe carefully and discontinue if it occurs. Cholesta jaundice occurred after OC and troleandomycin use. OC/cyclosporine combination may be hepatotoxic. Steroids may be poorly metabolized liver dysfunction and should be given cautiously. Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; megaloblas anemia has been reported. Serum folate may be depressed and may be exacerbated in post-OC pregnancy. Advise pathologist of OC use wh submitting specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after stopping for 2 months. These have be observed: increased BSP retention and other abnormalities in liver function tests; increased prothrombin and coagulation factors VII, VIII, I X; decreased antithrombin III, increased platelet aggregability; increased thyroid-binding globulin leading to increased circulating total thyro hormone (PBI, T^4); decreased T^3 uptake, unaltered free T^4, decreased pregnanediol excretion; reduced metyrapone response; increased blo transcortin, corticosteroid, triglyceride, phospholipid, reduced serum folate; impaired glucose tolerance; altered plasma trace minerals. Influen of prolonged OC use on pituitary, ovarian, adrenal, hepatic, or uterine function, or on immune response not established. OCs may mask ons of climacteric. Cervical chlamydial prevalence is increased; do not assume OC protects against chlamydial PID. *Information for patients.* S patient labeling. *Drug interactions:* OC effectiveness may be decreased and more BTB occur with rifampin, isoniazid, ampicillin, neomyc penicillin V, tetracycline, chloramphenicol, sulfonamides, nitrofurantoin, griseofulvin, barbiturates, phenytoin, carbamazepine, primidor phenylbutazone, analgesics, tranquilizers, antimigraines. OCs may alter effectiveness of oral anticoagulants, anticonvulsants, tranquilize tricyclic antidepressants, antihypertensives, theophylline, caffeine, vitamins, hypoglycemics, clofibrate, glucocorticoids, acetaminoph **Adverse reactions:** Increased risk of the following serious adverse reactions has been associated with OCs: thrombophlebitis a thrombosis; pulmonary embolism; arterial thromboembolism; Raynaud's disease, myocardial infarction; coronary thrombosis; cerebral thromb sis; cerebral hemorrhage; hypertension; gallbladder disease; Budd-Chiari syndrome; benign adenomas and other hepatic lesions, with or withc intra-abdominal bleeding, liver cancer, congenital abnormalities. There is evidence of association between the following and OCs, thou confirmatory studies have not been done: mesenteric thrombosis; neuro-ocular lesions, eg, retinal thrombosis and optic neuritis. The followi are believed drug related: nausea, vomiting, gastrointestinal symptoms, BTB, spotting, change in menstrual flow, dysmenorrhea, amenorrh during and after use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enlargeme secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, cholestatic jaundi migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate tolerance, vaginal candidiasis, change corneal curvature (steepening), intolerance to contact lenses. Association not confirmed or refuted for: premenstrual-like syndrome, catarac libido changes, chorea, appetite changes, cystitis-like syndrome, headache, paresthesia, nervousness, dizziness, auditory disturbances, rhinit fatigue, backache, hirsutism, scalp hair loss, erythema multiforme or nodosum, hemorrhagic eruption, herpes gestationis, hemolytic urem malignant hypertension, itching, vaginitis, porphyria, impaired renal function, acute renal failure, sometimes irreversible, PVCs, abnormal EK pulmonary hypertension, TTP, anemia, pancreatitis, hepatitis, colitis, Crohn's disease, gingivitis, dry socket, lupus erythematosus, rheumati arthritis, pituitary tumors (eg, adenoma) with amenorrhea and/or galactorrhea after use, malignant melanoma, endometrial, cervical, and brea carcinoma. **Acute overdosage:** Serious ill effects have not been reported after large acute doses of OCs in young children. Nausea a withdrawal bleeding might occur. **Important note: Complete prescribing information should be consulted prior to use a is available on request.**

GYNECOLOGY Principles & Practice

Edited by ZEV ROSENWAKS, MD, FRED BENJAMIN, MD, & MARTIN L. STONE, MD

You subscribe to journals to keep abreast of developments in gynecology. Don't waste time by using an obsolete clinical reference. The new **Gynecology** is the most current text you can own. It combines up-to-date information and sensible organization (each chapter stands alone so you can read just what you need at the moment), with contributions by eminent practitioners. Focusing on the patient and her clinical presentation, **Gynecology** is divided into 7 sections: basic concepts • menstrual abnormalities • puberty, development, and the menopause • normal and abnormal reproduction • PID • tumors and other diseases of the specific gynecologic organs • common presenting symptoms in gynecology. Thorough, comprehensive, timely, **Gynecology** is *the* text for practitioners and students alike.

PERINATOLOGISTS

Illinois, Chicago - Lutheran General Hospital is seeking two Perinatologists for an excellent opportunity in direct patient care, teaching and clinical research. Lutheran General is a 700-bed teaching hospital affiliated with the University of Illinois College of Medicine in Chicago. It is a designated tertiary care center with 3600 deliveries annually and has an active maternal transport service of over 200 a year. The Obstetrics and Gynecology Department has a residency program, and subspecialists in Gynecology/Endocrinology and Gynecology/Oncology. There is a 36-bed neonatal NICU with five neonatologists and a fellowship program. There is also a large referral service for genetic counseling and prenatal diagnoses, and more than 750 genetic amniocentesis are preformed annually. We have recently opened a large Perinatal Tertiary Center office.

The hospital is located in an attractive northwest suburb of Chicago. We offer a competitive salary with a generous incentive plan and an excellent benefit package.

Please send your curriculum vitae to:

The length of the human umbilical cord in twin pregnancies

Torgrim Soernes, M.D., and Trygve Bakke, M.D.
Norbyhagen, Norway

A current hypothesis on the linear growth of the umbilical cord states that cord length is a function of fetal intrauterine motor activity. If there is some type of intrauterine constraint, the tensile forces on the cord will be diminished, and cord length at term will be shorter than if no such constraint is present. One would expect that the voluntary movements of twins would develop under a constraint and that they would have less free space to move compared with single fetuses. If this hypothesis is valid, cord lengths of twins at term would be shorter than those of single pregnancy infants. We measured the cord lengths of 118 infants in 59 twin births and compared them with cord lengths in 9601 single pregnancies. We found that on the average, the umbilical cord length of the twins was 7.90 cm shorter than that of single pregnancy infants. (Am J Obstet Gynecol 1987;157:1229-30.)

Key words: Umbilical cord length, twins, fetal movements

Various reports of recent years[1-4] have pointed toward a new hypothesis concerning the length of the human umbilical cord at term. The hypothesis states that umbilical cord growth occurs as a result of the tensile forces placed on the cord, the most important of which is the movement of the fetus itself.

Experimental studies on animals have shown that if an intrauterine constraint is produced, such as oligohydramnios or fixation of the fetus in one of the uterine horns,[1,2] the fetus will tend to have among other defects a shorter umbilical cord than control animals.

The offspring of animals treated with a paralytic agent[1] during pregnancy, which presumably limits the spontaneous movements of the fetus, also show short cords.

Observations on human infants are few. Strikingly short cords have, however, been found in infants with either evidence of intrauterine compression (early amniotic rupture) or in infants with defects that seriously impair voluntary movements.[3]

We would expect the voluntary movements of fetuses in twin pregnancies to develop under such a constraint inasmuch as their intrauterine space is limited by the other twin. Twin studies, therefore, offer the opportunity to test the hypothesis on normal infants, that is, infants with no serious malformations.

Material and methods

We studied 59 twin births (118 infants) that took place in our hospital between 1979 and 1985. Infants with birth weights below 1000 gm were excluded from the study. The infants had their umbilical cord lengths measured at birth. In our hospital, the cord is routinely cut 2 cm from the fetal abdomen. The umbilical cord is then measured from this point to the placental surface.

The birth weight, birth presentation, and sex of each infant were also recorded.

The lengths of the umbilical cords of singleton infants were also measured, which gave us a control group of 9601 babies of single pregnancies during the same period.[4]

Results were considered statistically significant if $p < 0.001$.

Results

Of the 118 twin infants, 59 were boys and 59 girls.

There were 36 breech presentations and 82 vertex presentations. No statistically significant difference in cord length was found between these two groups.

No significant difference in cord length was found between the two sexes in this study.

The mean cord length of the 118 twins was 49.63 cm, whereas the mean cord length of the 9601 singleton infants was 57.52 cm. This result was statistically significant ($p < 0.001$).

Comment

Previous research[4,5] has demonstrated a sex difference in cord length among singleton infants in that on the average, male babies have slightly longer cords than do female babies. Furthermore, it has been recently shown that there is a tendency for infants born in the breech presentation to have shorter cords than babies born in the vertex presentation.[4]

We did not find any such differences in our twins.

However, because of the small number of cases in our study, we do not feel that any conclusions can be drawn from our study concerning these points.

The correlation between cord length and birth weight was found to be very small. This is consistent with the results of others.[6-8] Thus we assume that the comparison between twin and singleton cord length can be made regardless of different birth weights.

The salient point of our study is the demonstration that twins seem to have shorter umbilical cords than do single pregnancy infants; on the average the difference is 7.90 cm. At present, the most likely explanation for this is that the presence of the other twin in utero represents a limitation on intrauterine fetal movements.

Thus the results obtained in this study seem to lend credence to the hypothesis that cord lengths at birth can be viewed as a measure of the fetal level of intrauterine activity during the gestational period.

Prevention of recurrent idiopathic fetal growth retardation by low-dose aspirin and dipyridamole

Henk C. S. Wallenburg, M.D., Ph.D., and Nel Rotmans, B.Sc.

Rotterdam, The Netherlands

In a controlled, nonrandomized trial a treatment group of 24 multigravid women with a history of at least two previous pregnancies, all complicated by idiopathic fetal growth retardation and placental infarction, received 1 to 1.6 mg/kg aspirin and 225 mg dipyridamole daily from 16 to 34 weeks' gestation in a total of 30 pregnancies. The end-point measure of the study was birth weight related to gestational age. Results obtained in the treatment group were compared with those in 27 pregnancies of a control group of 24 multigravid women with a similar history of recurrent fetal growth retardation who received comparable antenatal care without low dose aspirin and dipyridamole. Fetal growth retardation occurred in 61% of the control pregnancies and in only 13% of treated pregnancies; severe fetal growth retardation was not observed in treated pregnancies, but it occurred in 27% of the control group. In treated women, platelet cyclo-oxygenase activity was suppressed to 5% to 10% of its pretreatment level, but no effect on vascular prostacyclin production was demonstrated. Treatment did not produce adverse effects in mothers or infants. Low-dose aspirin and dipyridamole direct prostacyclin/thromboxane A_2 balance in pregnancy to the dominance of prostacyclin and may thus prevent idiopathic uteroplacental insufficiency and fetal growth retardation in high-risk patients. (Am J Obstet Gynecol 1987;157:1230-5.)

Key words: Recurrent idiopathic fetal growth retardation, low-dose aspirin, dipyridamole, thromboxane, prostacyclin

Idiopathic fetal growth retardation, i.e., not attributable to fetal abnormality, maternal disease, or complications of pregnancy, is associated with reduced uteroplacental perfusion,[1] abnormal platelet behavior,[2,3] and uteroplacental arterial thrombosis resulting in placental infarction.[4] These pathologic processes have been explained by abnormal platelet-vessel and platelet-platelet interactions caused by an insufficient production of prostacyclin, resulting in a relative dominance of thromboxane A_2 in the uteroplacental cir-

From the Department of Obstetrics and Gynecology, Erasmus University Medical School.
Received for publication May 22, 1987; accepted June 17, 1987.

culation.[5] Thromboxane A_2, a powerful vasoconstrictor and stimulator of platelet aggregation, is the main cyclo-oxygenase metabolite of arachidonic acid in platelets and is also produced by various pregnancy-associated tissues.[6] A daily dose of aspirin as low as 1 to 2 mg/kg effectively inactivates platelet cyclo-oxygenase and inhibits platelet thromboxane A_2 synthesis, whereas the production of vascular prostacyclin, which has potent and opposite effects on vascular tone and platelet function, remains almost unaffected.[7] Low-dose aspirin may thus direct prostacyclin/thromboxane A_2 balance to the dominance of prostacyclin, an effect that may be potentiated by dipyridamole.[8] These considerations induced us to test the hypothesis that early antiplatelet therapy with a low dose of aspirin and dipyridamole may prevent uteroplacental thrombosis, placental infarction, and idiopathic fetal growth retardation in pregnant women judged to be at high risk on the basis of a history of recurrent severe fetal growth retardation.

Material and methods

General design. Initially we intended to perform a randomized, placebo-controlled trial, but we discovered at an early stage that patients with a history of recurrent severe fetal growth retardation, often with stillbirths, wanted treatment and were reluctant to take part in a randomized study, even without the use of placebo. It was then decided to use antiplatelet therapy in all patients eligible under previously established criteria. An external control group was composed of pregnant women without antiplatelet therapy who met the same criteria, received the same antenatal care, and were followed in the same hospitals as the treated patients. Primary end points in either group were fetal and neonatal mortality, birth weight, and gestational age at delivery. The study was approved by the hospital ethics committee.

Patients in treatment group. All Caucasian women referred to our outpatient clinic between January 1, 1983, and July 1, 1986, with a history of at least two pregnancies of more than 20 weeks' duration, all complicated by severe fetal growth retardation and placental infarction, without any other known complication of pregnancy or associated disease, were invited to take part in the study. None of the patients refused, and all gave their informed oral consent. The study was terminated when the treatment group included 24 patients, the same number as the control group. The obstetric history of these women included 80 singleton pregnancies, 20 of which were lost before 16 weeks' gestation. The remaining 60 pregnancies had resulted in delivery of growth-retarded babies, with the majority of birth weights below the 2.3 percentile of the distribution of normal weight for gestational age, corrected for parity and fetal sex (Table I). Only 11 babies were born alive, and 10 survived. No fetal malformations were observed, and all placentas showed extensive infarction.

*Number of events, with number of different patients in parentheses.

None of the women had a history of hemostatic disorders or thromboembolic disease. General physical examination before pregnancy revealed no abnormalities except mild and untreated essential hypertension in four women. Results of determination of the activated partial thromboplastin time, the dilute prothrombin time, and the kaolin clotting time suggested the presence of lupus anticoagulant[9] in two patients; cardiolipin antibody levels were not measured. Other laboratory tests did not reveal evidence of autoimmune, coagulation, or hepatic disorders or renal disease. The platelet life span was estimated by a nonradioisotopic technique[2] and was found to be normal (7 to 10 days) in all women.

Treatment protocol. After the women had become pregnant, the presence of a live fetus was confirmed by sonography at 12 to 14 weeks' gestation. The above tests were repeated. From 16 weeks' gestation onward all patients received one low dose of plain aspirin daily (1 mg/kg/day, rounded off to the nearest 10 mg) and 75 mg dipyridamole, three times daily. The capacity of platelets to synthesize thromboxane A_2 in vitro on stimulation with thrombin was assessed by determination of the production of malondialdehyde.[2] Malondialdehyde production was measured every 2 to 3 weeks, and the dose of aspirin was adjusted to suppress malondialdehyde production to 5% to 10% of its pretreatment value. In addition, the four patients with essential hypertension received methyldopa (750 to 1000 mg/day); no other treatment was given except oral iron supplements, and diets were unrestricted. All patients were explicitly told not to use any other aspirin-containing compounds.

At 28 weeks' gestation the production of prostacyclin

and thromboxane A_2 was assessed by determination in venous plasma of their stable metabolites, 6-oxo-prostaglandin $F_{1\alpha}$ and thromboxane B_2, respectively. Values obtained in the same gestational period from 30 randomly selected pregnant women with uncomplicated pregnancies resulting in the term delivery of live infants with birth weights above the tenth percentile were used as controls. The eicosanoids were measured by radioimmunoassay after solvent extraction with commercial kits (Seragen, Inc., Boston, Massachusetts). The platelet life span was again determined at 32 to 34 weeks' gestation, if the patients were still pregnant, and treatment was then terminated.

None of the patients smoked during pregnancy. Antenatal care included serial sonography and cardiotocographic monitoring of the fetus in the third trimester. All patients remained ambulatory unless obstetric complications occurred. The investigators acted as observers; all clinical decisions were made by the patients' own obstetricians in the four hospitals involved.

Patients in control group. The obstetric records of the University Hospital Dijkzigt and of the affiliated Ikazia Hospital were searched for patients with recurrent idiopathic fetal growth retardation delivered after 20 weeks' gestation between January 1, 1977, and December 31, 1982. We found 68 Caucasian women who had at least two pregnancies and were delivered of growth-retarded babies with infarcted placentas in all of them and whose records indicated that fetal growth retardation could not be attributed to fetal abnormality, complications of pregnancy, or maternal disease. Follow-up data obtained from 64 women showed that 40 had not become pregnant again, whereas 24 women had had one or more subsequent pregnancies between 1983 and 1987. These 24 women composed the control group; the history of their 60 index pregnancies is summarized in Table I. Seven of 50 babies were stillborn. In their subsequent pregnancies the women received the same antenatal care as the women in the treatment group, and in the same hospitals, except the University Hospital Dijkzigt. Various therapeutic regimens were prescribed, including prophylactic antihypertensive medication and bedrest, but they received no aspirin and dipyridamole. Two of the women smoked during pregnancy.

Statistical analysis. Differences in relative frequencies between treatment and control groups were analyzed with the χ^2 or Fisher's exact test. The Wilcoxon rank-sum test was used to analyze differences in measured variables between the two groups. A p value <0.05 was regarded as significant.

Results

Patients. Comparison of both groups shows that the total number of index pregnancies (abortions excluded) and the distribution of parity are similar. However, fetal death and severe fetal growth retardation (<2.3 percentile) occurred significantly more often in the index pregnancies of the treatment group than in those of the control group (Table I). In the treatment group four patients had two and one patient had three subsequent pregnancies, so we report the results of 30 treated pregnancies. In the control group three women had two subsequent pregnancies, resulting in a total of 27 pregnancies (Table II).

Course and outcome of pregnancy. In the control group the number of viable pregnancies complicated by severe fetal growth retardation (<2.3 percentile) was seven (27%) and the total percentage of fetal growth retardation (<tenth percentile) was 61.5. This is in con-

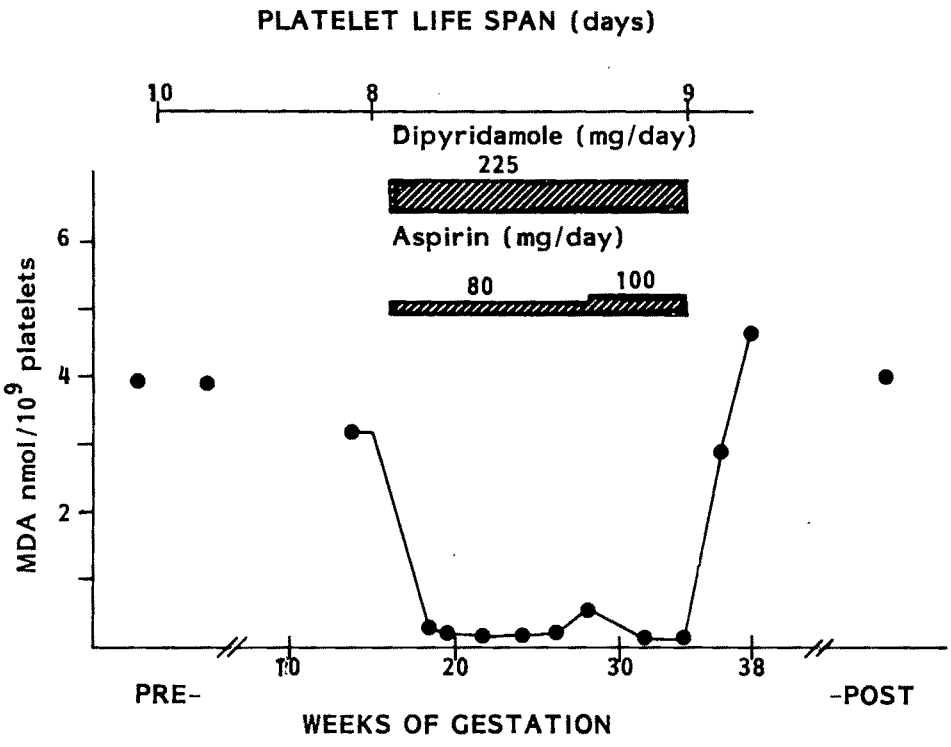

Fig. 1. Platelet life span and malondialdehyde production in one patient before, during, and after pregnancy. This pregnancy ended successfully at 38 weeks.

trast with the results obtained in the 30 treated pregnancies, in which no severe fetal growth retardation occurred and the total percentage of fetal growth retardation was 13.3; the difference is statistically significant ($p < 0.002$). The difference between groups remains significant when only the first subsequent pregnancies are considered. The two infants with birth weights between the 2.3 and fifth percentiles in the treatment group were delivered of the two patients with lupus anticoagulant.

In the treatment group two pregnancies were complicated by mild pregnancy-associated hypertension (diastolic blood pressure 90 to 100 mm Hg) in the third trimester, after treatment had been stopped. In the control group mild hypertension occurred in four pregnancies. In the treatment group small areas of infarction (5% to 10% of placental volume) were found in five placentas, two of which came from the two patients with lupus anticoagulant, and one was delivered by a patient with mild pregnancy-associated hypertension. The placentas of the seven severely growth-retarded infants in the control group were moderately to severely infarcted. Unfortunately, not all placentas of the other infants in the control group were systemically examined.

There was one fetal death in the treatment group, in a 24-year-old woman, gravida 3, with an uncomplicated pregnancy until 27 weeks' amenorrhea, when abruptio placentae occurred. The stillborn baby had a normal weight for gestational age of 950 gm. The median duration of pregnancy was 1 week shorter in the treatment group than in the control group, but this difference is not statistically significant. Because of the high number of repeat cesarean sections performed during labor, the total cesarean section rate was two times higher in the treatment than in the control group (not significant).

In nine pregnancies a reduction of platelet life span of 2 days or more as compared with nonpregnant values was found at 14 weeks' gestation. In seven of these patients the platelet life span could again be determined at 34 weeks, and appeared to have returned to prepregnancy values. The dose of aspirin needed to suppress platelet malondialdehyde production to the desired 5% to 10% of the pretreatment level ranged between 40 and 100 (median 80) mg/day. In 18 pregnancies the aspirin requirement did not change throughout pregnancy, and in 12 pregnancies it increased slightly to a maximum dose of 1.6 mg/kg/day in one patient. The response of platelet malondialdehyde production to treatment in one patient is shown in Fig. 1.

Plasma concentration of 6-oxo-prostaglandin $F_{1\alpha}$ (51.7 ± 9.8 ng/L) in treated patients was not significantly different from control values (47.4 ± 13.5 ng/L), whereas plasma thromboxane B_2 levels in treated

patients (18.6 ± 6.1 ng/L) were significantly ($p < 0.01$) lower than those in controls (38.4 ± 12.2 ng/L).

No adverse effects were noted in the treatment group, and no excessive bleeding was observed during delivery or cesarean section in seven women who still received treatment at that time. None of the infants in either group showed congenital abnormalities. In the treatment group one infant, born at 27 weeks, developed severe respiratory distress but recovered. Periods of moderate respiratory distress occurred in four other premature babies in the treatment group and in three infants in the control group. No other neonatal complications were encountered in either group, in particular no hemorrhagic complications in the treatment group. All infants are thriving.

Comment

A physiologic balance between prostacyclin and thromboxane A_2 appears to be important in the regulation of vascular tone and platelet-vessel and platelet-platelet interactions, not only in the systemic but also in the uteroplacental circulation.[6] An imbalance in favor of thromboxane A_2 may be expected to interfere with the physiologic adaptation of the maternal circulation, which may become clinically apparent as pregnancy-induced hypertension or preeclampsia, fetal growth retardation, or both.[5, 10] The factors that govern prostacyclin synthesis in normal pregnancy have not yet been elucidated, and for that reason it is not known why prostacyclin production may become relatively deficient in some women. It is known, however, that prostacyclin synthesis may be inhibited by a circulating lupus anticoagulant, a condition associated with repeated abortions, fetal growth retardation, and fetal death.[11]

Our results show that a low daily dose of aspirin (1 to 1.6 mg/kg) combined with dipyridamole, 225 mg/day, markedly suppressed platelet thromboxane synthesis, as indicated by a fall in thrombin-induced malondialdehyde production to 5% to 10% of the pretreatment level. Also, the low plasma thromboxane B_2 values in the treated group indicate marked inhibition of thromboxane synthesis, whereas plasma concentrations of 6-oxo-prostaglandin $F_{1\alpha}$ were not significantly lower than in controls. Thus the combination of low-dose aspirin and dipyridamole directed the maternal prostacyclin/thromboxane A_2 balance to the dominance of prostacyclin. The results of various studies suggest that this effect is mainly caused by the low dose of aspirin,[7, 8] which inhibits platelet cyclo-oxygenase in the presystemic (portal) circulation.[12] However, our study design does not permit assessment of the relative contribution of dipyridamole, a phosphodiesterase inhibitor considered to potentiate the action of aspirin by delaying the breakdown of cyclic adenosine monophosphate, by rendering platelets more sensitive to prostacyclin and perhaps by stimulating prostacyclin synthesis.[8]

Our method of selection of patients to be treated led to inclusion of the most severe cases of recurrent fetal growth retardation in the treatment group, whereas the histories of controls were significantly less complicated. Despite this bias in favor of the controls, 61% of control patients had another low birth weight infant, in comparison with only 13% in the treated group. The high recurrence rate in the control group is in agreement with results from other studies.[13] The significantly better outcome in the treatment group cannot be attributed to differences between groups with respect to ethnic background, smoking habits, antenatal care, or duration of gestation at delivery; this strongly suggests that low-dose aspirin and dipyridamole given from 16 to 34 weeks' gestation improves uteroplacental perfusion and fetal growth and prevents placental infarction. It may be of significance that in nine pregnancies a marked reduction in platelet life span was already apparent at 14 weeks' gestation, probably because of increased platelet consumption in the uteroplacental vascular bed caused by formation of thrombi.[2] The observed return to normal values at 34 weeks suggests reversal of the pathologic platelet-vessel wall interaction. The two cases of rather severe fetal growth retardation occurred in patients with evidence of circulating lupus anticoagulant. In these patients suppression of anticoagulant activity with prednisone, in addition to the antiplatelet therapy, might have further improved fetal growth.[11]

Our study supports data from a randomized, but not double-blind, trial reported by Beaufils et al.,[14] who treated 52 patients at high risk for preeclampsia and/or fetal growth retardation with 150 mg aspirin and 300 mg dipyridamole daily from 3 months of gestation until delivery. No severe fetal growth retardation (less than third percentile) occurred in the treated women, compared with seven cases in 50 untreated high-risk control patients.

The low dose of aspirin used in the second and part of the third trimester in combination with dipyridamole did not cause any apparent adverse effects in mother or fetus. Neonatal hemorrhagic complications have been reported after high doses of aspirin (5 to 15 gm) ingested by the mother in the 5 days before delivery.[15] There is no evidence that this occurs with the much lower doses we used, and most patients were delivered at least 1 week after the end of the treatment. The small number of proved cases of in utero constriction of the ductus arteriosus after maternal ingestion of aspirin[16] have also been associated with doses that were much higher than we used.

We realize that a randomized clinical trial with in-

ternal controls would have been the method of choice for our study. For reasons already stated, we had to use external controls. Although such a study will support less strong inferences than a randomized trial, it still has a role in clinical investigation.[17] We feel that the results of our study show sufficient promise to justify further controlled clinical trials to establish the possible benefit of low-dose aspirin, with or without dipyridamole, in the prevention of recurrent idiopathic fetal growth retardation.

We are indebted to Dr. P. K. Flu, Ikazia Hospital, Rotterdam, and Drs. M. B. Graal and A. P. van Leeuwen for their invaluable help in gathering the control group. We thank Dr. H. J. T. Coelingh Bennink and Dr. H. W. Bruinse, University Hospital, Utrecht, and Dr. A. Verhoeff, Zuiderziekenhuis, Rotterdam, for allowing us to study and treat their patients.

Caffeine-cigarette interaction on fetal growth

Louise Beaulac-Baillargeon, Ph.D., and Carole Desrosiers, B.Sc.(Pharm.), M.Sc.
Ste-Foy, Quebec, Canada

The influence of caffeine and cigarette consumption on fetal growth during pregnancy was studied retrospectively in 913 newborn infants. Analysis of variance was adjusted for length of gestation and sex. A significant caffeine-cigarette interaction was found on birth weight ($F = 85.4$, $p < 0.01$). Among women smoking 15 cigarettes or more per day, birth weight was 206 gm (±57.7 gm) lighter for babies whose mothers consumed 300 mg or more of caffeine per day. Head circumference and length of the newborns were affected only by cigarette smoking. Another caffeine-cigarette interaction was observed on placental weight ($F = 15.0$, $p < 0.01$). Among women who consumed less than 300 mg of caffeine daily, placental weight increased with cigarette consumption. However, it diminished ($p < 0.05$) among women smoking 15 cigarettes or more per day if they consumed 300 mg or more of caffeine daily. This is the first time that such interactions were found to influence birth and placental weights, indicating that the concomitant consumption of caffeine and cigarette constitutes a higher risk for the developing fetus. (Am J Obstet Gynecol 1987;157:1236-40.)

Key words: Caffeine, cigarette smoking, fetus, pregnancy, fetal growth

The caffeine, cigarette, and alcohol consumption of mothers during pregnancy has been the subject of many studies of its effects on fetal growth. Because these substances can easily reach the fetus by placental transfer, it is of prime importance to study the effect of interaction of these substances on fetal growth.

The influence of smoking on birth weight is well known. In fact, birth weight is reported to be inversely proportional to the number of cigarettes smoked by the mother, and this effect is independent on other factors related to the variation in birth weight.[1] The length of the newborn is also reduced when the mother smokes, and some authors have observed a decrease in head circumference.[2] Placental weight is not affected by smoking, but the number of cigarettes smoked has been correlated with hypovascular and atrophic microscopic changes in placental villi[3] and deterioration of placental perfusion type.[4] The reduction in uteroplacental circulation caused by the vasoconstricting effect of nicotine[4] and the relative fetal hypoxia caused by the increase of carbon monoxide concentrations in the fetus[5] are two factors responsible for the decrease in fetal growth observed among babies born to smokers.

On the other hand, maternal alcoholism has been related to a series of physical and neurologic abnormalities of newborns that in 1973 Jones and Smith[6] termed "fetal alcohol syndrome." A significant clinical reduction of newborn weight is observed only at a consumption level higher than 30 ml of absolute alcohol per day.[7]

During pregnancy, the elimination kinetic profile of caffeine was reported to be modified. In fact, Aldridge et al.[8] reported an increase in the half-life of caffeine from 5.3 hours before pregnancy to 18.1 hours during the last two trimesters of pregnancy. These values return to normal soon during the postpartum period. This increase in the half-life of caffeine in the mother coincides with the period during which fetal growth is exponential so that an accumulation of this substance represents a potential risk for the fetus and the placenta, which is responsible for the transfer of nutrients.

To date, no well-controlled study has found that caffeine influences human birth weight. However, it has been demonstrated that a unique dose of 200 mg of caffeine, which is equivalent to two to three cups of coffee, administered to the mother significantly reduces blood flow in placental villi and increases maternal serum epinephrine levels.[9] This effect of caffeine on placental circulation is quite similar to that observed after cigarette consumption.

Smoking is often associated with high caffeine intake, and this has also been confirmed for pregnant women.[10] However, the influence of that concomitant intake on fetal growth was not fully investigated. The association of these two consumption habits could represent a greater risk of disturbing the full development of the fetus. However, to date research has not fully investigated this hypothesis because the effects of caffeine and cigarette consumption on fetal growth have been studied separately.

The effects of caffeine and cigarettes on placental circulation raise the assumption that these substances

can act in an additive or synergistic way on fetal growth. The main objective of this study was to evaluate the independent effect and the interaction of caffeine and cigarette on weight, head circumference, length of the newborn, placental weight, and placental ratio (placental weight/birth weight × 100).

Methodology

All women delivering at either Centre Hospitalier Chauveau or Hôpital St-François d'Assise in Québec City, Canada, during a 5-month period from February to July 1985 were requested to complete a questionnaire on their caffeine, cigarette, and alcohol consumption habits during pregnancy. Of these 35 women refused to participate while 1014 women entered the study. This low refusal rate of 3% is not thought to bias the results. Standardized verbal and written information was given along with the questionnaires. Data collection was completed by a review of the medical and obstetric records of the mother and baby. The consumption pattern of caffeine, cigarettes, and alcohol of these women during pregnancy has been the subject of a previous publication.[11]

The questionnaire gathered information about the socioeconomic status, participation at prenatal classes, parity, obstetric history, weight before and at the end of pregnancy, height, health problems, and pattern of consumption of caffeine, cigarettes, and alcohol during pregnancy. The reported intake of these substances represents an average across pregnancy.

The caffeine content of coffee, tea, cola, and chocolate used is that reported by the quantitative analysis of Gilbert et al.,[12] and the publication of Graham.[13] The amount of caffeine varied depending on the substance consumed: coffee: expresso = 170 mg/cup of 180 ml, filter or percolator = 110 mg/cup, instant = 75 mg/cup, and decaffeinated = 1 mg/cup; tea: bag = 50 mg/cup and leaves or instant = 30 mg/cup; chocolate = 40 mg/bar of 40 gm; cola: diet or regular = 45 mg/180 ml. These values were used to calculate total caffeine consumption by adding the intake from coffee, tea, cola, and chocolate. Cigarette consumption represents the number of cigarettes smoked per day. Alcohol consumption was calculated in milliliters of absolute alcohol consumed per day. Beer (350 ml), wine (120 ml), appetizer (60 ml), and spirits/digestive (30 ml) contained 15, 13, 13, and 15 ml, respectively, of absolute alcohol per serving.

To study the influence of caffeine, cigarette, and alcohol consumption on fetal growth and exclude other major factors affecting fetal growth, it was necessary to exclude 101 subjects from the results analysis: multiple pregnancies (n = 16), mothers suffering from preeclampsia and chronic hypertension (n = 51), diabetes (n = 8), organic heart disease (n = 5), congenital spherocytosis (n = 1), Val Kecklinhausen (hyperparathyroidia) (n = 1), hypoglycemia (n = 3), babies with major malformations (n = 11), and stillbirths (n = 5).

Table I. Physical characteristics of mothers and newborns

Characteristics	*Mean ± SD*
Mothers	
Weight before pregnancy (kg)	56.3 ± 9.7
Weight at the end of pregnancy (kg)	69.6 ± 10.5
Weight gain (kg)	13.3 ± 4.4
Height (cm)	160.7 ± 6.0
Length of gestation (wk)	39.4 ± 1.6
Placental weight	526.1 ± 121.0
Newborns	
Birth weight (gm)	3352.1 ± 496.3
Head circumference (cm)	34.5 ± 1.5
Length (cm)	51.0 ± 2.3

Statistical analysis was done by means of the statistical analysis system. Level of significance was fixed at 0.05. Analysis of variance for unbalanced groups was done by the introduction of independent variables: caffeine, cigarette, and alcohol consumption and combinations of these variables adjusted for length of gestation and the sex of the babies. The consumption of these substances was divided as follow: alcohol: <2, 2 to 5.9, ≥6 ml of absolute alcohol per day; cigarettes: 0, 1 to 14, ≥15/day; and caffeine <300 and ≥300 mg/day. Dependent variables included birth weight, head circumference, length of newborns, placental weight, and placental ratio. Tukey-Kramer's test for unbalanced groups was used to define the influence of different levels of consumption on fetal growth. Reported means for birth weight, head circumference, and length were adjusted for length of gestation and the sex of the babies, both of which were unevenly distributed in the subgroups studied. Placental weight was adjusted for length of gestation only since it did not vary with the sex of the babies.

Results

After data collection, 101 subjects were excluded since they did not meet the inclusion criteria mentioned. Results are presented for the remaining 913 subjects.

Physical characteristics of babies and mothers are presented in Table I.

Alcohol at doses consumed by women in the present study had no significant effect on the studied parameters. Mean absolute alcohol consumption of this population was 1.5 ml (SD = ±3.2 ml) per day, which represented about three servings of alcoholic beverages per month.

Subjects were then grouped according to caffeine and cigarette consumption. Caffeine consumption was

Table II. Groups according to the caffeine and cigarette consumption of the mothers

Consumption level			*Mean consumption*	
Caffeine (mg/day)	*Cigarettes (No./day)*	*No. of subjects*	*Caffeine (mg/day) mean ± SD*	*Cigarettes (No./day) mean ± SD*
<300	0	536	100.8 ± 83.2	0
<300	1-14	128	119.3 ± 90.6	7.6 ± 3.8
<300	>15	114	135.2 ± 86.5	20.3 ± 5.4
≥300	0	42	407.8 ± 222.7	0
≥300	1-14	24	423.9 ± 116.9	9.3 ± 3.4
≥300	>15	69	442.2 ± 142.7	22.8 ± 6.8

divided into two categories: (1) subjects whose consumption was less than 300 mg/day and (2) those whose daily consumption was greater than 300 mg/day. Among these two categories, women were divided according to their cigarette consumption, either 0, one to 14, or 15 or more per day. For each of these six groups, Table II shows the number of subjects and the mean daily consumption of caffeine and cigarettes.

At the end of pregnancy, smokers represented 36.7% of the study population. Whereas 15.8% of the women who smoked one to 14 cigarettes/day and 37.7% of those who smoked 15 or more cigarettes daily consumed 300 mg or more of caffeine daily, only 7.3% of nonsmokers belonged to the latter category. Among the 135 women (14.8% of the population) whose daily consumption of caffeine rose to 300 mg or more, 68.9% smoked.

Birth weight. Analysis of variance revealed an influence of cigarette ($F = 32.3$, $p < 0.01$) and caffeine-cigarette interaction ($F = 5.8$, $p < 0.01$) on birth weight. For nonsmokers, mean birth weight of babies adjusted for length of gestation and sex of babies was 3441.9 gm (SEM = 16.8 gm). This weight was significantly reduced ($p < 0.05$) for babies born to mothers who smoked; it was 3204.4 gm (SEM = ±39.0 gm) and 3141.7 gm (SEM = ±28.8 gm) for a consumption of one to 14 and 15 or more cigarettes per day, respectively. Fig. 1 presents mean birth weight of babies divided according to maternal caffeine and cigarette consumption. All four smoking subgroups had mean birth weights significantly lower than both nonsmoking subgroups. For nonsmokers and women who smoked one to 14 cigarettes daily, the birth weight was not statistically different with a caffeine consumption less than or greater than 300 mg/day. However, among women smoking 15 cigarettes or more per day, the birth weight of babies of those women who consumed 300 mg or more caffeine daily was significantly ($p < 0.05$) lighter than that of babies whose mothers consumed less caffeine. The difference in birth weight of babies between these two groups was 206 gm (SEM = ±57.7 gm).

When we consider both caffeine and cigarette consumption, the birth weight of babies born to women who smoked 15 cigarettes or more per day was significantly reduced if the mother consumed 300 mg of caffeine or more daily.

Head circumference. Head circumference was influenced by cigarette consumption ($F = 8.2$, $p < 0.01$) but not by caffeine consumption. No caffeine-cigarette interaction was found. Head circumference of babies born to nonsmokers was 34.6 cm (SEM = ±0.06 cm), and it diminished significantly ($p < 0.05$) for babies of mothers who smoked, being 34.3 cm (SEM = ±0.11 cm) and 34.1 cm (SEM = ±0.11 cm) in newborns whose mothers smoked one to 14 and 15 or more cigarettes per day, respectively.

Length. Length of babies was also influenced by cigarette consumption ($F = 17.8$, $p < 0.01$), but again there was no interaction between cigarette smoking and caffeine consumption. Babies born to nonsmokers had a mean length of 51.3 cm (SEM = ±0.09 cm), whereas those born to mothers who smoked one to 14 and 15 or more cigarettes per day were 50.7 cm (SEM = ±0.16 cm) and 50.3 cm (SEM = ±0.15 cm) long, respectively.

Placental weight. Placental and birth weights underwent a caffeine-cigarette interaction ($F = 8.9$, $p < 0.01$). There was no significant difference between placental weight of nonsmokers and placental weight of the two other groups of smokers.

However, when we compared this weight between smokers groups according to their caffeine consumption, a dose-related interaction was seen. Fig. 2 shows mean placental weight adjusted for length of gestation for each consumption group. Among women who consumed less than 300 mg of caffeine daily, placental weight was significantly higher for those who smoked 15 cigarettes or more per day (mean ± SEM = 566.6 ± 12.5 gm) as opposed to nonsmokers (mean ± SEM = 517.5 ± 4.8 gm) ($p < 0.05$) and smokers of one to 14 cigarettes per day (mean ± SEM = 521.2 ± 10.4 gm).

Among women who smoked 15 cigarettes or more per day, placental weight was significantly reduced for those who consumed 300 mg or more of caffeine daily compared with those whose caffeine consumption was

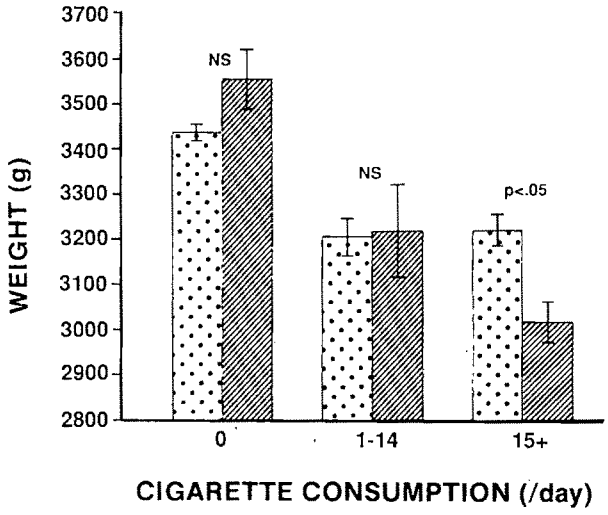

Fig. 1. Effect of caffeine-cigarette interaction on birth weight. Means (±SEM) are adjusted for the length of gestation and sex of newborns. (▩ = Caffeine consumption <300 mg/day; ▨ = caffeine consumption ≥300 mg/day.)

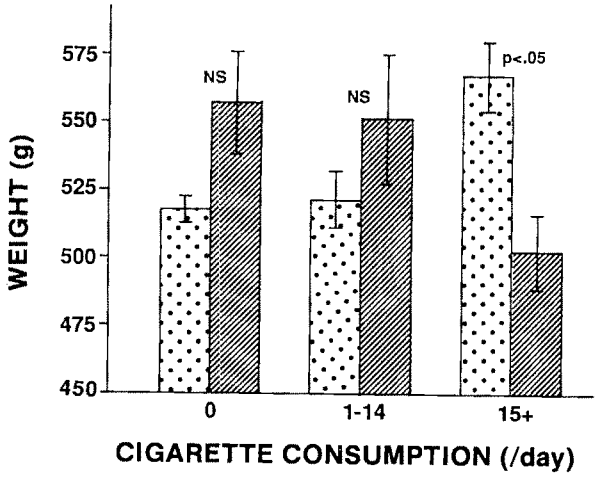

Fig. 2. Effect of caffeine-cigarette interaction on placental weight. Means (±SEM) are adjusted for the length of gestation. (□ = Caffeine consumption <300 mg/day; ▨ = caffeine consumption ≥300 mg/day.)

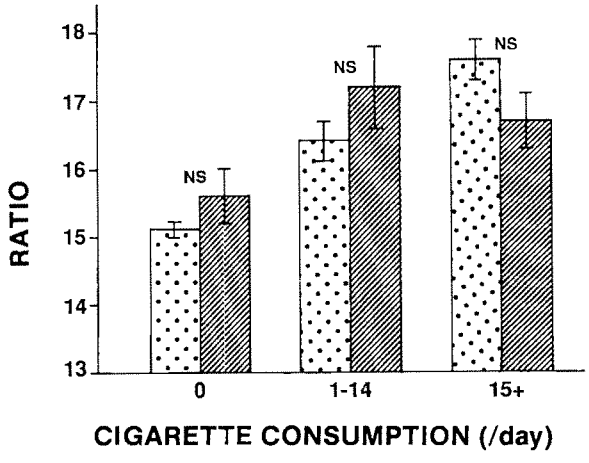

Fig. 3. Effect of caffeine-cigarette interaction on placental ratio. Means (±SEM) are adjusted for the length of gestation and sex of newborns. (▩ = Caffeine consumption <300 mg/day; ▨ = caffeine consumption ≥300 mg/day.)

less than 300 mg/day ($p < 0.05$); placental weight was 502.3 gm (SEM = ±13.8 gm) and 566.6 gm (SEM = ±12.5 gm), respectively.

Placental ratio. The ratio of placental weight to birth weight was affected by cigarette consumption ($F = 12.8$, $p < 0.01$) and underwent a caffeine-cigarette interaction ($F = 3.3$, $p < 0.05$) (Fig. 3). Placental ratio increased with cigarette consumption, going from 15.1 (SEM = ±0.12) for nonsmokers to 16.5 (SEM = ±0.26) and 17.3 (SEM = ±0.26) for women who smoked one to 14 and 15 or more cigarettes per day, respectively. This reflects the increase in placental weight and the decrease in birth weight observed with an increase in the number of cigarettes smoked.

Considering both caffeine and cigarette consumption, the placental ratio increased significantly ($p < 0.05$) for every consumption level of cigarettes for women who consumed less than 300 mg of caffeine/day. However, for women who consumed 300 mg or more of caffeine daily, there was no significant difference in placental ratio according to cigarette consumption. Among women who smoked 15 or more cigarettes a day, the placental ratio was not statistically different with a caffeine consumption of less than or greater than 300 mg/day, since both birth and placental weights diminished when caffeine consumption was 300 mg or higher.

Comment

This study confirms that cigarette consumption during pregnancy reduces weight, head circumference, and length of the newborn infant. Placental weight is not affected by smoking. These results are consistent with those of other studies.[3] Since placental weight is stable and birth weight diminishes with cigarette consumption, an increase in the placental ratio results. This effect was also observed by Wingerd et al.[14] Wilson[15] suggested that smoking causes chronic fetal hypoxia, which results in a reduction of fetal growth, and that the relative placental hypertrophy is compensatory. Even if cigarette consumption does not seem to affect placental growth negatively in terms of weight, it has been shown that it produces a reduction of placental blood flow[3, 4] and that it increases morphologic anomalies of the placenta.[16] Many changes in the ultrastructure of the placenta of smokers have been observed[17] and might induce a decrease in metabolism and diffusion through the placental barrier.

Linn et al.[18] concluded that independent of cigarette consumption, the incidence of low birth weight was not affected by maternal consumption of coffee or tea. Van den Berg[10] observed that the percentage of babies weighing 2500 gm or less was 9% in smokers who consumed more than six cups of coffee per day. Because 4.4% of the nonsmokers consumed the same quantity of coffee daily and because the latter percentage was equal to that observed in the total cohort, he attributed the difference entirely to cigarette consumption without considering that this effect might be caused by the association between caffeine and cigarettes. These authors have calculated caffeine consumption in the number of cups of coffee per day without taking into account the eventual consumption of decaffeinated coffee. In addition, tea consumption was transformed into cups of coffee without correcting for its smaller caffeine content. Other sources of caffeine, such as cola and chocolate, were not considered.

The results of our study show that caffeine consumption during pregnancy has a negative effect on the birth weight of babies born to smokers of 15 or more cigarettes per day. Doses of 300 mg or more of caffeine per day in these women accentuate the decrease caused by smoking. It is the first time that such an effect has been demonstrated. Moreover, the interaction between caffeine consumption and smoking affects placental weight in a particular manner. For women who consume less than 300 mg of caffeine/day, the placenta could compensate for the effect of cigarettes by real hypertrophy. Nevertheless, for women who smoke 15 or more cigarettes a day and consume 300 or more mg of caffeine daily, placental weight is reduced compared with women who consume less caffeine.

To explain the underlying mechanisms of the caffeine-cigarette interaction on birth and placental weights, further microscopic and ultrastructural studies are required since morphometric measures alone do not permit complete definition of the functional capacity of the placenta.

We thank the direction and the staff from the Departments of Gynecology and Obstetrics of Centre Hospitalier Chauveau and Hôpital St-François d'Assise for their collaboration in this study.

BRIEF SUMMARY

INDICATIONS:
FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS:
FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS:
General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS:
Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION:
Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

The effect of smoking on placental and fetal zinc status

P. M. Kuhnert, Ph.D., B. R. Kuhnert, Ph.D., P. Erhard, B.S., W. T. Brashear, M.S., S. L. Groh-Wargo, M.S., and S. Webster, M.S.

Cleveland, Ohio

Previous studies have reported a cadmium/zinc interaction in cadmium-exposed pregnant animals that results in (1) increased placental cadmium levels, (2) increased placental zinc levels, and (3) decreased placental zinc transport. This study was carried out to determine whether zinc status would be affected in pregnant women exposed to cadmium through cigarette smoke. Atomic absorption spectroscopy was used to determine the levels of cadmium and zinc; 65 pregnant women who smoke and 84 who do not smoke were studied. Our data reveal that increased cadmium levels in pregnant women as the result of smoking increase placental zinc levels and decrease cord red blood cell zinc levels. Significantly higher levels of both cadmium and zinc were found in the placentas of pregnant women who smoke; moreover, stepwise multiple regression showed that maternal whole blood cadmium levels predicted placental zinc levels. In regard to cord blood, a significant 9% decrease in the red blood cell zinc level was observed in infants of mothers who smoke and this decrease was correlated with smoking activity, as evaluated by measuring plasma levels of thiocyanate. Also cord red blood cell zinc levels were found to correlate with placental zinc levels in nonsmokers but not in smokers. Overall, our data show that a cadmium/zinc interaction does take place in the maternal-fetal-placental unit of pregnant women who smoke and results in less favorable zinc status in the infants. (Am J Obstet Gynecol 1987;157:1241-6.)

Key words: Smoking, placental zinc, fetal zinc

Zinc nutritional status has a profound influence on the biochemistry and toxicology of cadmium. One reason for this is that cadmium and zinc often act antagonistically in biologic systems; for example, cadmium acts as an antagonist to zinc in zinc-requiring metalloenzymes, for instance, carbonic anhydrase,[1] alkaline phosphates,[2] and others.[3] Another reason is that metallothionein, which is produced in response to cadmium exposure, binds both cadmium and zinc; thus, if zinc levels are marginally adequate, zinc status may be aggravated by the binding and storage of zinc by cadmium-induced metallothionein. Finally, an inadequate zinc nutritional status can influence the absorption and tissue uptake of cadmium, thereby increasing the probability of a toxic effect due to cadmium.[4]

Pregnant women may be particularly susceptible to this cadmium/zinc interaction. They are susceptible because their zinc intake is generally substantially lower than the Recommended Daily Allowance of zinc during pregnancy[5] and significant associations have been reported between fetomaternal complications and plasma zinc levels.[5] Even more vulnerable, however, is the pregnant woman who smokes cigarettes. The average cigarette contains as much as 1 μg of cadmium, and heavy smokers may have an intake of 20 μg/day or more as the result of smoking, in addition to the average daily intake of 50 μg/day from dietary sources. Thus decreased zinc nutritional status and increased cadmium intake may promote a cadmium/zinc interaction in pregnant women who smoke.

The magnitude of this cadmium/zinc interaction in pregnant women who smoke is of course important since it could influence fetal growth and development. Low zinc concentrations in maternal blood and cord blood have been related to abnormal events in parturition, intrauterine growth retardation, and increased incidences of congenital malformations in humans.[5] Moreover, previous research on pregnant animals has clearly shown that this interaction occurs between cadmium and zinc and can result in the fetus receiving less zinc.[5]

Accordingly, we investigated the zinc status and cadmium levels of pregnant women who smoke. Our primary purpose was to determine whether the cadmium levels were related to zinc status in the mother and fetus. We report herein the results of our investigation.

Methods and material

Patients and collection of samples. Sixty-five pregnant women who smoke and 84 who do not smoke and their fetuses were included in this study. The only selection criteria were that the mothers resided in or very near Cleveland, Ohio, and were delivered of their infants at Cleveland Metropolitan General Hospital. They were not selected with regard to prenatal or intrapartum medical problems, although in depth clinical information was recorded. Informed consent for this study was obtained from the subjects in the appropriate manner.

Samples of blood were obtained from the mothers within an hour of delivery and from the umbilical cord immediately after delivery. Samples of 10 ml were procured in separate heparinized polypropylene syringes from the antecubital vein of the mother and umbilical cord vein of the infant. Samples of placental tissue were obtained after several cotyledons had been perfused with 2 L of cold 0.9% saline solution to remove excess blood, and the membranes and blood vessels were removed. Each sample was then stored frozen until analyzed for levels of whole blood cadmium (maternal blood only), placental cadmium, placental zinc, plasma zinc, and red blood cell zinc. Maternal plasma was also analyzed for thiocyanate, which was used in conjunction with questionnaires for assessing smoking behavior.

Zinc intake in a random subgroup of the population (29 smokers, 37 nonsmokers) was assessed by diet history at term. The diet history included a 7-day food frequency assessment that was verified for accuracy by a 24-hour recall. Food sources known to be the major contributors of zinc in the diet (for example, meat, seafood, eggs, dairy products, dried beans and peas, and whole grain breads and cereals) were quantified and an estimate of weekly zinc intake in milligrams was calculated.

Determination of cadmium, zinc, and thiocyanate levels. The samples of blood and placental tissue were prepared for analysis of cadmium by means of acid digestion. The digestion mixture was concentrated Ultrex (J. T. Baker, Phillipsburg, New Jersey) nitric acid and hydrogen peroxide. The details of this procedure were previously described by us.[7]

An atomic absorption spectrophotometer (Model 560, Perkin Elmer Corp., Norwalk, Connecticut) equipped with a deuterium background corrector and a graphite furnace (Model HGA-2200, Perkin Elmer Corp.) was used for the cadmium analyses.

In contrast to the analysis of cadmium, flame atomic absorption analysis was used for the analysis of zinc. Red blood cell and plasma zinc was analyzed after a 1:4 dilution with deionized water. Glycerol was added

to the blank and standards to approximately match the viscosity of the diluted plasma. Placental zinc was analyzed after acid digestion as described under cadmium analysis.

Plasma thiocyanate, a byproduct of the metabolism of cyanide in cigarette smoke, was measured by means of the procedure described by Pettigrew and Fell.[8] Patients with thiocyanate values ≤59 μmol/L were defined as nonsmokers and those with values of ≥60 μmol/L were defined as smokers in the few cases where information obtained from the clinical record was not consistent with the thiocyanate data. Passive smokers were considered nonsmokers unless the thiocyanate values were ≥60. Maternal, fetal, and placental alkaline phosphatase levels were quantitated with the method of Doellgast and Meis.[9]

Data analysis. Statistical analyses were performed with the BMDP UCLA statistical software package and a DEC Vax 11/750 computer (Digital Equipment Corporation, Maynard, Massachusetts) with a Unix operating system. Data analysis consisted of descriptive statistics, *t* tests, and simple correlations to produce an overview of significant differences between the groups and interrelationships between the various biochemical indices. The χ^2 analysis was used to test for differences in clinical parameters between the two groups. Then stepwise multiple regression techniques were used to examine the interactions between cadmium exposure and zinc status while controlling for statistically confounding variables such as maternal age, parity, race, delivery method, vitamin intake, and diabetes. In some cases (placental cadmium, placental zinc, thiocyanate), the variables were not normally distributed. In these cases, log transformations were used. Statistical significance was the same regardless of whether a log transformation was used. Significance was accepted at $p < 0.05$.

Results

The characteristics of the mothers and infants in this study are shown in Tables I and II, respectively. The smokers and nonsmokers are classified separately. Table I shows that the maternal population groups had similar characteristics except for the proportion of white patients who smoked; a significantly higher proportion of the white patients were smokers. Table II shows that the mean birth weight of the infants of mothers who smoked was less than that of the infants of mothers who did not smoke ($t = 4.7$; $p < 0.0001$). Also more small-for-dates infants were born to mothers who smoked than to mothers who did not smoke. These findings are in agreement with previous studies concerning pregnant women who smoke.

The blood levels of thiocyanate of the two study populations are shown in Table III. The mean levels in the mothers who smoked were significantly higher than those in the nonsmokers.

Illustrated in Fig. 1 and Table III are the relative levels of cadmium found in maternal blood and in the placentas of smokers and nonsmokers. The percent increase in cadmium in the whole blood of smokers was 64%; the percent increase in placental cadmium was 45%. In both smokers and nonsmokers more cadmium was found in the placentas than in the blood. These

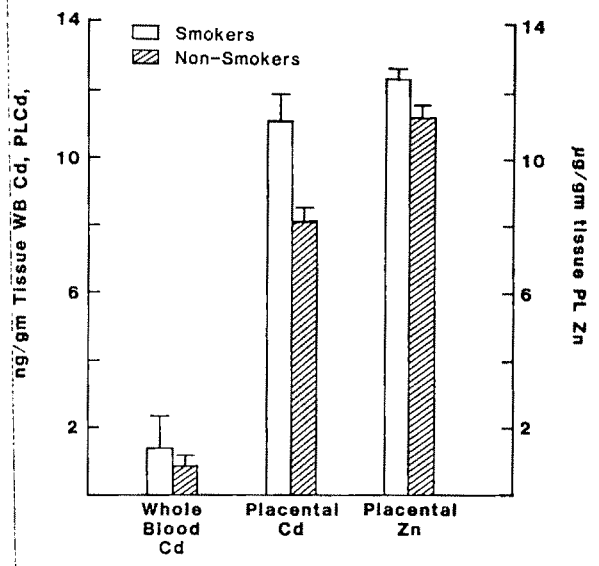

Fig. 1. The effect of smoking on whole blood cadmium, placental cadmium, and placental zinc levels.

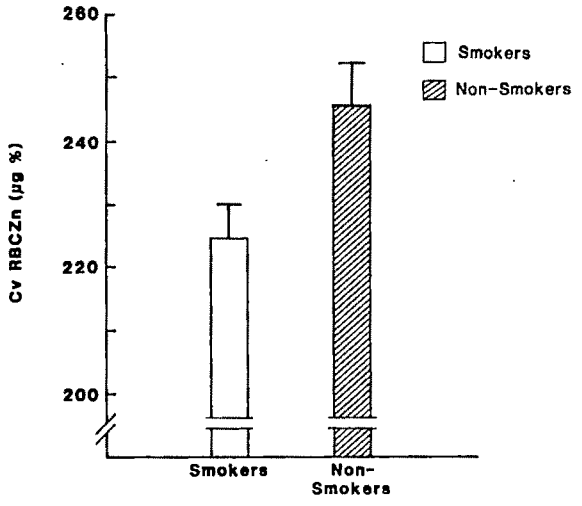

Fig. 2. Cord vein red blood cell zinc levels in smokers and nonsmokers.

findings are in agreement with previous studies concerning cadmium exposure in pregnant women who smoke.[6, 10-12]

The zinc status of smokers and nonsmokers and that of their infants (as assessed by measurements of plasma and red blood cell zinc levels and alkaline phosphatase activity) is compared in Table IV. No significant differences were observed in the mothers. Moreover, diet histories verified that there was no difference in zinc intake between pregnant women who smoked and those who did not. The average daily intake of zinc was 10.4 mg. A major finding of the study was the 9% decrease in the red blood cell zinc level in the cord blood of infants of mothers who smoke (Fig. 2); this difference is statistically significant.

A comparison of the zinc status of the mothers and infants shows that the infants had plasma zinc and alkaline phosphatase levels that were approximately one third higher than those of their mothers; on the other hand, the red blood cell zinc levels of the infants were approximately five times lower than those observed in the mothers.

Comparisons of the levels of zinc in the placentas of smokers and nonsmokers are shown in Table IV and Fig. 1. Significantly higher levels of zinc were found in the placentas of pregnant women who smoked. The significantly higher levels of placental zinc correlated with significantly higher levels of alkaline phosphatase in the placenta.

In smokers, the significant predictor of both placental zinc and placental cadmium by stepwise multiple regression was maternal whole blood cadmium. In nonsmokers, the maternal whole blood cadmium level predicted the placental cadmium level but not the placental zinc level. These data are summarized in Table V, which shows the F value, degrees of freedom, and p value for each analysis.

Since a 9% decrease in the red blood cell Zn level was observed in the cords of infants of mothers who smoke, the relationships between the biochemical variables and cord vein red blood cell zinc levels were examined. Significant predictors of the cord vein red blood cell zinc level, as assessed by stepwise multiple regression, were different in the smoking and nonsmoking groups. In smokers, thiocyanate was the strongest predictor of the cord vein red blood cell zinc level. The simple correlation showed that the relationship was negative, that is, the more thiocyanate in maternal plasma, the less zinc in the red blood cells of the infant. In nonsmokers, placental zinc was the strongest predictor of cord vein red blood cell zinc. The simple correlation showed that the relationship was positive, that is, the more placental zinc, the more cord vein red blood cell zinc. These data are summarized in Table VI, which shows the F value, degrees of freedom, p value, and r value for each analysis.

Comment

The principal purpose of this study was to determine whether the increased levels of cadmium found in pregnant women who smoke affects the distribution of zinc in the maternal-fetal-placental unit. Our data show that increased cadmium levels as the result of smoking influence the levels of zinc in the placenta and cord blood and that this effect of cadmium is significant even though the absolute increase in cadmium as the result of smoking is small.

To determine the effect of increased cadmium ex-

posure on zinc status in pregnant women who smoke, we first verified that our study population of pregnant smokers and nonsmokers (with similar clinical characteristics) had similar levels of zinc intake. This was done by comparing diet histories and several indices of zinc status of the two groups. Our data showed that there was no difference in zinc intake between the smokers and the nonsmokers and that there was no difference in plasma zinc and red blood cell zinc levels. The data also showed that zinc intake of both groups was about 50% below the Recommended Daily Allowance for zinc during pregnancy, as reported by other investigators studying healthy pregnant patients.[5] However, since both groups had decreased zinc intake and were similar in all other respects, a comparison could be made in regard to the effect of cadmium exposure on zinc status.

The cadmium exposure of our study population as the result of smoking was similar to that reported by us[6] and by others.[10-12] We observed a 64% increase in whole blood cadmium and a 45% increase in placental cadmium in the present study. The percent increase in placental cadmium reported to date has ranged from 26[10] to 400.[11, 12] The values differ, of course, depending on the study population and on the analytic techniques used. However, all the studies agree that there is a substantial increase in cadmium in the placentas of pregnant women who smoke.

Increased exposure to cadmium and decreased zinc intake, as found in our pregnant smokers, are conditions that favor an effect of smoking on zinc status. Data supporting this are based on studies involving animals. For example, studies by Webb and Samarawickrama[13] on rats show that maternal cadmium exposure causes fetal zinc deficiency and that this is one mechanism of the teratogenic effects of cadmium. By giving cadmium to pregnant rats these workers were able to show a dose-related decrease in fetal uptake of zinc. Additional evidence that cadmium can induce fetal zinc deficiency was reported by Daston.[14] This author showed that coadministration of zinc almost eliminated the severe lesions in the fetal lung when the pregnant rat was given cadmium. Although the levels of cadmium in these studies are much higher than we observed in our study population, the threshold for such effects has not been established for animals or humans. Moreover, our data suggest that a cadmium/zinc interaction takes place in the maternal-fetal-placental unit of pregnant women who smoke.

One aspect of our data that suggests a cadmium/zinc interaction and an effect of smoking on zinc status is the 10% increase in the level of zinc in the placentas of pregnant women who smoke. This is suggestive because it is likely that the increased levels of cadmium as the result of smoking induce the production of metallothionein, a low molecular weight protein that binds both cadmium and zinc. With the increased production of metallothionein there is an increased binding of cadmium and zinc and consequently a sequestering of these metals in the placenta. Although this has not been specifically studied in the placenta, autopsy studies of the kidney have shown that zinc levels increase in the kidney cortex with increasing concentrations of cadmium, and this increase is almost equimolar to the increase in cadmium.[15] Support for this interpretation is also provided by our statistical analysis, which shows that in smokers maternal whole blood cadmium levels are predictive not only of the placental cadmium levels but also of the placental zinc levels.

Another aspect of our data that suggests an effect of smoking on zinc status is the 9% decrease in red blood cell zinc observed in the cords of infants of mothers who smoke. This decrease was found to correlate with the levels of thiocyanate (an index of the number of cigarettes smoked) in maternal blood. Thus the greater the number of cigarettes smoked, the lower the level

of red blood cell zinc observed in cord blood. An explanation for this, which is supported by our data, is that zinc bound to metallothionein is accumulating in the placenta and that this binding may reduce the amount of zinc available to the fetus. Another possibility is that less zinc is being transported by the placenta to the fetus; this has been shown to occur in cadmium-injected pregnant rats.[16] Regardless of the explanation, however, the data show that a cadmium/zinc interaction occurring in pregnant women who smoke may be harmful to the fetus since the decrease in cord red blood cell zinc is related to decreased birth weight in the infants of smokers.[17]

Finally, additional evidence of the effect of smoking on fetal zinc status was noted in our data when the relationship between placental zinc levels and cord vein red blood cell zinc levels was examined. The data show a positive correlation between placental zinc and cord vein red blood cell zinc in nonsmokers; in smokers, however, this relationship was not found. The cadmium/zinc interaction, that is, the altered metabolism of zinc brought about by increased cadmium intake due to cigarette smoking, may explain the lack of this correlation in smokers.

The effect of smoking on zinc status in the placenta and fetus may have no health significance if the availability of zinc is above the real requirement. On the other hand, this interaction may be detrimental to the fetus where zinc status is marginal. Additional studies are needed to clarify this point and to determine if zinc supplementation can counteract these changes in tissue levels (as it does in animals). Nevertheless, our studies show that there is an adverse effect of smoking on zinc status in the placenta and fetus, that is, a cadmium/zinc interaction does take place in the maternal-fetal-placental unit of pregnant women who smoke. This finding provides one additional reason for discouraging pregnant women from smoking.

The relationship between cadmium, zinc, and birth weight in pregnant women who smoke

B. R. Kuhnert, Ph.D., P. M. Kuhnert, Ph.D., S. Debanne, Ph.D., and T. G. Williams, M.S.
Cleveland, Ohio

It is universally accepted that smoking during pregnancy results in decreased infant birth weight. However, the mechanism for decreased birth weight is not completely understood. This study tested the hypothesis that the cadmium/zinc interaction in the maternal-fetal-placental unit of the mother who smokes could be related to birth weight. Thiocyanate was used as the index of smoking status and atomic absorption spectroscopy was used to determine trace elements. Results show that cord vein red blood cell zinc and maternal whole blood cadmium levels are significant predictors of infant birth weight when variance that is due to clinical fctors and thiocyanate is controlled with stepwise multiple regression techniques (n = 202). Bivariate correlation techniques showed that the factors affecting birth weight were different in the smoking and nonsmoking groups. For example, in nonsmokers (n = 125), the cord vein red blood cell zinc level was positively related to birth weight. In smokers (n = 77), maternal whole blood cadmium, placental cadmium, and placental zinc levels were negatively related to birth weight; the ratio of placental zinc to placental cadmium and the cord vein red blood cell zinc level were positively related to birth weight. The results suggest that increased maternal cadmium and decreased cord vein red blood cell zinc levels in infants of smokers may be significant clinically since increased maternal whole blood cadmium and decreased cord vein red blood cell zinc levels are both significantly related to decreased birth weight.
(AM J OBSTET GYNECOL 1987;157:1247-51.)

Key words: Smoking, cadmium, zinc, birth weight

Smoking during pregnancy results in infants with lowered birth weights.[1] The traditional explanation for the smaller infants has been the hypoxia from carbon monoxide and constriction of the uterine blood vessels from nicotine.[2, 3] However, there are many other compounds in cigarette smoke that may be harmful. One of these is the toxic element cadmium. Each cigarette smoked contributes approximately 1 μg of cadmium to the body's burden of cadmium.[4]

An explanation for the smaller infants is suggested by the interaction between cadmium and zinc in the placenta of mothers who smoke.[5] Zinc is required for many aspects of fetal growth and development.[6] We have recently reported that the cadmium in cigarette smoke may decrease the transfer of zinc across the human placenta.[5] Pregnant women who smoke have higher levels of cadmium and zinc in the placenta and their infants have significantly lower levels of zinc in the red blood cells.[5] Furthermore, cadmium may have adverse effects because it competes with zinc in zinc-requiring metalloenzymes.

The purpose of this study was to test the hypothesis that the cadmium and the altered zinc metabolism reported in the maternal-fetal-placental unit of the mother who smokes could be related to lowered infant birth weight.

Methods and material

Patients and collection of samples. Seventy-seven pregnant women who smoke and 125 who do not and their fetuses were included in this study. The only selection criteria for this survey were that the mothers resided in or very near Cleveland, Ohio, and were delivered of their infants at Cleveland Metropolitan General Hospital. They were not selected with regard to prenatal or intrapartum medical problems, although in depth clinical information was recorded. Informed consent for this study was obtained from the patients in the appropriate manner. The clinical characteristics of most of these patients and the outcomes of their pregnancies have been described previously.[5]

Samples of blood were obtained from the mothers

Placental zinc/cadmium ratio*	Zinc-cadmium interaction

*Significant independent variables subsequently used for stepwise multiple regression analyses.
†Not significant but used because the ratio of placental zinc to placental cadmium was significant.

within an hour of delivery and from the umbilical cord immediately after delivery. Placental samples were obtained immediately after delivery. Samples were analyzed for determination of whole blood cadmium (maternal blood only), placental cadmium, placental zinc, plasma zinc, and red blood cell zinc. The procedures for sample collection, analysis of the elements by atomic absorption spectrometry, and determination of smoking status with thiocyanate have been reported previously.[5] Smoking status was determined by analysis of plasma thiocyanate, by the clinical record, and by questionnaire.

Data analysis. Statistical analyses were performed with the BMDP statistical software package[7] and a Dec Vax 11/750 computer with a Unix operating system. Descriptive statistics, Student's *t* test, and simple correlations were used to get an overview of distributional properties, significant bivariate differences between the groups (smokers and nonsmokers), and interrelationships between the various clinical and biochemical indices.

Stepwise multiple regression techniques were then used to examine the dependency of birth weight on cadmium exposure and zinc status, after adjusting for significant potential confounding clinical variables such as maternal age, parity, gravidity, race, and maternal red blood cell count. Variables used for both bivariate analyses and stepwise multiple regression analyses are listed in Table I. The sample size was adequate for study of the final 12 variables by stepwise multiple regression.

Placental zinc was not statistically significant with bivariate analysis but was used for stepwise multiple regression analyses because the placental zinc/placental cadmium ratio was significant. This ratio is defined as the ratio of the concentration of placental zinc divided by the concentration of placental cadmium multiplied by 1000.

For variables not normally distributed (placental cadmium, placental zinc, and thiocyanate), log transformations were used where appropriate. Statistical significance was the same regardless of whether a transformed variable was used. Significance was accepted at $p < 0.05$.

The variables selected for multivariate analyses were those yielding significant bivariate associations with the outcome variables of interest (Table I). These analyses were done first on both smokers and nonsmokers together, in order to produce a large range of birth weights and thiocyanate values, and then were also carried out on smokers and nonsmokers separately.

Results

Results of the biochemical determinations have been reported previously.[5] Significant relationships were found between the altered disposition of zinc and cadmium due to smoking and the decreased birth weights in infants of smokers (3143 ± 554 versus 3534 ± 555 gm in nonsmokers). The results of the biochemical variables have been reported previously.[5] Table II shows the results of the multiple regression analyses with birth

*Not significant ($p < 0.05$).
†Nonwhite infants of smoking mothers weighed slightly less than white infants.

weight as the dependent variable. Only predictors reaching significance at the 5% level for at least one group are shown. After controlling for the clinical variables, thiocyanate (that is whether or not the mother smoked) accounted for a large percentage of the variance ($F[7,193] = 33.1$, $p < 0.001$) that remained. After thiocyanate, the strongest predictors of birth weight were maternal whole blood cadmium ($F[8,192] = 7.1$, $p < 0.001$) and cord vein red blood cell zinc ($F[9,191] = 4.2$, $p < 0.001$). All of the variables (including those that were not significant) accounted for more than 30% of the variance in birth weight that was found.

With the use of simple correlations, it could be shown that there were different relationships between the biochemical variables and birth weight, depending on smoking status. This is the major finding of the study. Table III shows the significant simple correlations found with birth weight. It can be seen that maternal whole blood cadmium and thiocyanate are negatively related to birth weight in smokers. Furthermore, cord vein red blood cell zinc and the ratio of placental zinc to placental cadmium are positively related to birth weight, that is, the more zinc in the cord vein red blood cells or the more zinc than cadmium in the placenta, the greater the birth weight. In nonsmokers, the only

biochemical variable related to birth weight was cord vein red blood cell zinc.

Comment

Cigarette smoking during pregnancy results in a decrease in infant birth weight.[1] Smoking may actually be the most important risk factor for fetal growth disturbances. Thus it is not surprising that this phenomenon has recently been given the name "fetal tobacco syndrome."[8]

The mechanism for the decrease in birth weight is not completely understood but is thought to be due to hypoxia and vasoconstriction in the uterine vessels.[2,3] The results of this study suggest that cadmium and its interference with fetal zinc uptake may be related to the decrease in birth weight in infants of mothers who smoke during pregnancy.

While it is well known that zinc is needed for fetal growth in animals,[6] investigators have not always been able to show a relationship between maternal or fetal zinc status and birth weight in human infants. This was particularly true when the index of zinc status was serum zinc. For example, small for gestational age infants did not have serum zinc concentrations that were different from those of larger infants.[9-11] However, when leukocyte zinc was used as the index of zinc status, it could be shown that infants with prolonged intrauterine growth retardation had less zinc than normal infants.[11] We have shown in this study that cord vein red blood cell zinc is highly correlated with birth weight and have shown previously that it is negatively correlated with maternal smoking.[5] Thus it appears that if cord vein red blood cell zinc is used as the index of zinc status, the infant's zinc status may be related to both smoking and decreased birth weight.

Plasma zinc has been questioned as a valid indicator of zinc status since it represents only a small fraction of total body zinc.[6,11] Furthermore, it is known to decrease as the result of normal physiologic changes that occur during pregnancy.[6] Red blood cell zinc has been more difficult to measure but it probably represents a storage form of zinc and is a more stable index of zinc status.

The technique of multiple regression allows for control of confounding clinical variables and independent examination of the effects of related biochemical variables on an outcome variable. It was particularly useful in the present study because of the known confounding effects of clinical variables on birth weight and because several of the biochemical variables are related. For example both cord vein red blood cell zinc and whole blood cadmium are influenced by how much the mother smokes (that is, the thiocyanate level).[5] By use of multiple regression, it was possible to control clinical variables and for thiocyanate and then see if there was still a relationship between cadmium or zinc and birth weight. The results show that both maternal whole blood cadmium and cord vein red blood cell zinc predict birth weight independent of thiocyanate. The fact that these variables are altered by smoking suggests that this may be one explanation for the decreased birth weight in infants of smokers.

We have previously shown that increased maternal whole blood cadmium[12] and cadmium-zinc interaction due to smoking result in increased levels of both cadmium and zinc in the placenta and decreased cord vein red blood cell zinc in the infant.[5] The results of this study suggest that this biochemical interaction is clinically significant because increased maternal whole blood cadmium and decreased cord vein red blood cell zinc both are correlated with decreased birth weight.

Using simple correlations to look at smokers and nonsmokers separately suggested that the groups differ significantly in terms of factors related to birth weight. In nonsmokers, only cord vein red blood cell zinc was related to birth weight. In the smokers, negative relationships were found between birth weight and the cadmium and zinc variables. In other words, the more the mother smokes as measured by thiocyanate, the higher the levels of whole blood cadmium, placental cadmium, and placental zinc[5] and the lower the birth weight. This appears to be due to the trapping of zinc in the placenta, which results in less zinc in the infants' red blood cells and theoretically less zinc available for growth.

The ratio of placental zinc to placental cadmium was also positively related to infant birth weight in smokers. This is of interest because zinc is present in the placenta in much higher quantities than is cadmium. Zinc is measured in micrograms per gram of tissue, whereas cadmium is measured in nanograms per gram of tissue. Thus there is a thousandfold difference in the concentrations of the two metals. Nevertheless, the ratio of placental zinc to placental cadmium is related to birth weight. This attests to the importance of the cadmium-zinc interaction and to the toxicity of cadmium.

In addition to affecting birth weight directly, smoking may affect pregnancy in other ways that can also affect birth weight. For example, the length of gestation may be shortened. In order to minimize other effects on infant birth weight, standardized birth weight is often used to study the effect of smoking. This index is based on an expected mean birth weight for a historical population at a particular gestational age. By using stepwise multiple regression and controlling for the clinical factors such as gestational age, we accomplished the same thing. We were then able to look for a relationship between cord vein red blood cell zinc and the absolute size of the infant regardless of gestational

age. Our findings support the relationship between cadmium-zinc interaction and decreased birth weight in infants of smokers.

It has historically been difficult to prove causality between smoking and disease or smoking and lowered birth weight. However, with time, enough evidence has accumulated that little doubt remains as to the adverse effects of smoking. Similarly, it is difficult to show causality in this study between the cadmium and zinc variables and decreased birth weight. However, there are definitely relationships between the variables contributed primarily by smoking, that is, cadmium, and those known to be affected by smoking, that is, cord vein red blood cell zinc,[5] and birth weight. Furthermore, the relationships vary depending on the mother's smoking status during pregnancy; birth weights in smokers are predicted by the smoking variables. This was particularly evident in Table III. These associations make sense physiologically and are supported by the cadmium-zinc interaction recently reported in the human placenta by us[5] and previously reported in animal studies.[6] We hope that our studies will stimulate other trace element studies in pregnant smokers to confirm these relationships.

The results of this study suggest that zinc supplementation should be studied as a partial means of intervention for the pregnant smoker who cannot quit. The results of this study do not suggest that physicians should immediately start giving zinc to pregnant women who smoke. There are several reasons for this caveat: First, supplementation with zinc may disrupt the absorption of other essential elements, such as copper.[13] Second, the large amounts of iron or folic acid that are often given during pregnancy may interfere with the absorption of a zinc supplement.[14,15] Third, if the mothers are not zinc deficient, a supplement may have no effect on infant birth weight.[16] Thus a carefully controlled study that monitors zinc status and zinc, cadmium, and metallothionein levels in the placenta as well as birth weight needs to be done before universal zinc supplementation can be recommended for pregnant smokers.

Pleural effusions and pulmonary hypoplasia

Ramon A. Castillo, M.D., Lawrence D. Devoe, M.D. Greer Falls, M.D., Gerald B. Holzman, M.D., Hamid A. Hadi, M.D., and Hossam E. Fadel, M.D.
Augusta, Georgia

Nine cases of fetuses with pleural effusions are presented in which the diagnosis was made by ultrasound before the thirtieth week of gestation. A ratio of lung span to hemithorax diameter was calculated and ranged from 0.44 to 0.77 (mean 0.60). At autopsy, pulmonary hypoplasia was confirmed in all cases by criteria based on the ratio of lung weight to total body weight. Because pleural effusions occurring in the midtrimester can be detected and may lead to pulmonary hypoplasia, consideration should be given to definitive in utero therapy when no other major fetal abnormality is detected. (AM J OBSTET GYNECOL 1987; 157:1252-5.)

Key words: Effusions, pulmonary hypoplasia, ultrasound

Increased use of real-time ultrasonography has resulted in early prenatal recognition of major fetal abnormalities. Prenatal detection of pleural effusions was first reported by Defoort and Thiery[1] in 1978; its association with pulmonary hypoplasia was later reported in 1981 by Bovicelli et al.[2] Subsequent reports have linked this condition with other anomalies or the syndrome of hydrops fetalis.[3, 4] The presence of pleural effusions is associated with a high incidence of fetal morbidity and mortality mainly because of the frequent coexistence of pulmonary hypoplasia. Although pulmonary hypoplasia is a histopathologic diagnosis, attempts have been made to correlate it with ultrasonographic findings.[6]

We now present a series of nine fetuses with significant pleural effusions diagnosed in utero before the thirtieth week of gestation. No prenatal management was undertaken and the effusions were quantified by use of the lung-thoracic ratio. Because all fetuses had pulmonary hypoplasia the natural history of this disorder and the relationship between the ultrasound findings of pleural effusions and the development of fetal lung hypoplasia are discussed.

Patients and methods

Table I is a summary of nine fetuses with bilateral pleural effusions studied in the Obstetrical Ultrasound Section of the Medical College of Georgia in the 2-year period from July 1984 to August 1986. During the initial ultrasound examination a detailed anatomic survey was performed and quantification of each pleural effusion was done. This measurement, described previously,[4] consists of a ratio between the lung span and the fetal hemithorax determined in transverse or longitudinal views. Also as part of the prenatal evaluation the following tests were performed: amniocentesis for fetal karyotype, delta optical density at 450 nm, and viral cultures. Analysis of maternal blood included a Kleihauer-Betke test, complete hemogram, blood type and antibody screen, glucose screen, and hemoglobin electrophoresis.

Results

Four pregnancies were electively terminated and one patient underwent induction of labor after intrauterine fetal death had been documented. In the other four cases, the fetuses were delivered alive after the spontaneous onset of labor. Autopsy was performed in each case and the results of each examination are presented in Table I. In three cases no anatomic abnormalities were found and there were no fluid accumulations in other serous cavities (Cases 1, 5, and 6). In Cases 2 and 8, no significant structural abnormalities were present, but a karyotypic disorder was found. In the remainder at least one other major anomaly was present although a direct association between these abnormalities and pulmonary hypoplasia could not be established.

All fetuses were found to have pulmonary hypoplasia as defined by the criteria of Reale and Esterly.[7] This definition consists of a ratio of total lung weight to total body weight that falls more than 2 SD below the normal value of 0.022 ± 0.002 and is constant throughout gestation.

Comment

The development of the fetal lung encompasses different stages that have characteristic anatomic findings:

(1) the glandular stage between the fifth and the seventeenth weeks, (2) the canalicular stage between the thirteenth and the twenty-fifth weeks, (3) the alveolar phase that occurs from the twenty-fourth week to approximately the eighth decade of life.[8] The intrauterine environment must provide a number of factors for these stages to proceed uneventfully; adequate amniotic fluid volume; presence of fetal breathing activity, intact muscular activity, and adequate intrathoracic and extrathoracic volumes that are capable of allowing the lung to expand. When one or more of these factors are not present or are significantly altered, the result is a spectrum of disorders ranging from minimal lung disease to severe pulmonary hypoplasia.[3, 4, 8]

In the present series, each fetus had bilateral pleural effusions that were quantified by the lung-thoracic ratio. In our institution any accumulation of fluid that can be quantified with this measurement is considered to be "significant." In Case 5 this measurement was repeated at 32 and 36 weeks' gestation with an objective decrease in the amount of the effusions (Fig. 1, *A* to *C*). Despite the reduction in pleural fluid in this fetus, the histopathologic findings were consistent with lung hypoplasia (Fig. 1, *D*). Therefore regardless of the cause the fluid accumulations appear to function as space-occupying lesions and restrict the development of the fetal lung, a sequence of events that was recognized by Potter in 1952 in fetuses with diaphragmatic hernias.[7]

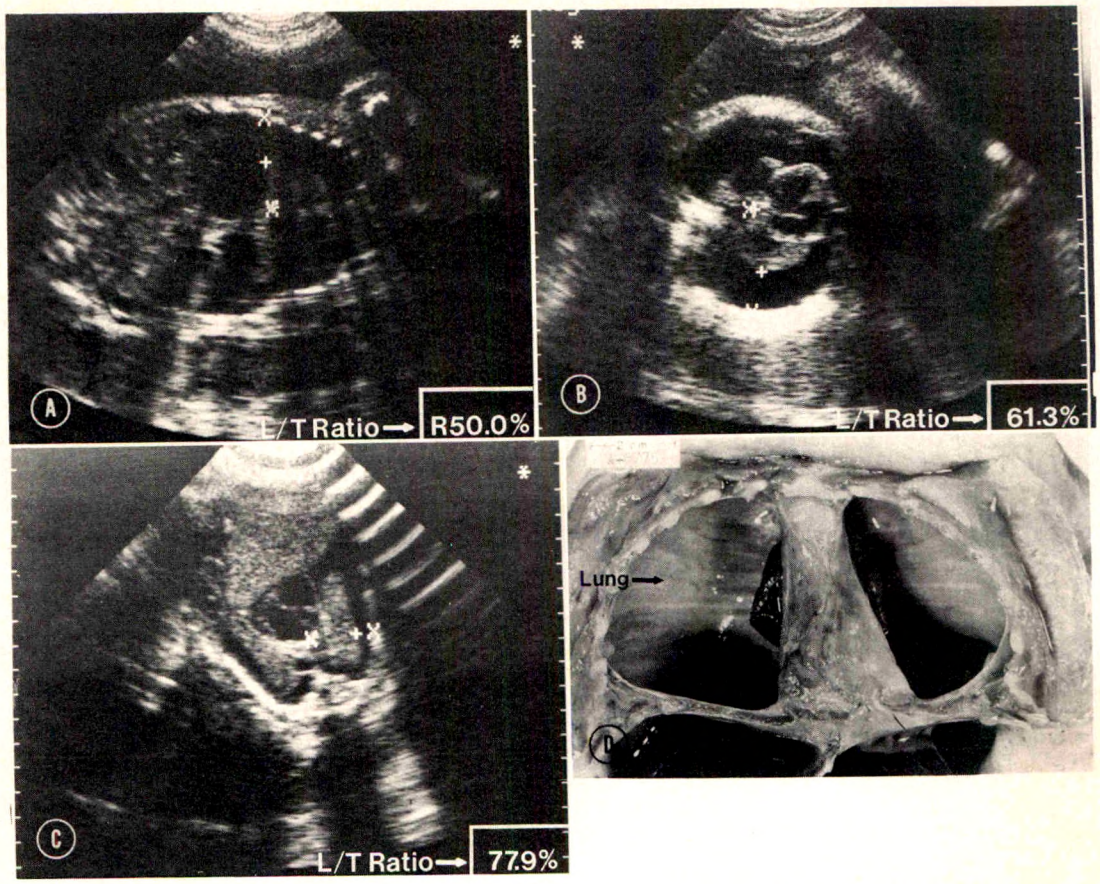

Fig. 1. Lung-thoracic ratios obtained at *(A)* 30 weeks', *(B)* 32 weeks', and *(C)* 36 weeks' gestation. Despite a reduction in the amount of pleural fluid the lungs were hypoplastic *(D)* with a ratio of lung weight to total body weight *(L/T ratio)* of 0.009.

However, it is clear that the sole presence of these effusions at birth is not enough to establish severe lung damage since adequate pulmonay function in some of these babies has been reported.[9] It seems that the gestational age at which these effusions develop may play a critical role in the development of severe and irreversible damage to the fetal lung.

Studies of morphologic lung development as well as a case report of persistent hypoplasia of the lung after repair of congenital diaphragmatic hernia suggest that such lesions appearing in the alveolar phase of lung development may not produce irreversible damage. Once the process is corrected, the development of alveoli may proceed although these may be significantly decreased in number.[8-10] These same studies and our histopathologic analysis of the nine hypoplastic lungs show that there are some changes in the bronchial tree and in the arterioles of hypoplastic lungs that indicate that the onset of this process occurred before the twenty-fourth to twenty-sixth week of gestation. These changes are reduced bronchial airway generation and increased muscularity of pulmonary blood vessels. Therefore it is suggested that if there are significant fluid accumulations in the pleural space before the alveolar phase and if this fluid accumulation persists throughout the remainder of pregnancy, the fetal lung could be irreversibly damaged.

Since 1982 at least five fetuses have been treated in utero by decompression of the thorax by means of either repeated pleural taps or placement of a pleural amniotic shunt.[5, 11-15] While the fetal outcomes are not always good, our experience suggests that untreated significant pleural effusions detected by the second trimester of pregnancy can lead to significant lung hypoplasia and perinatal death.

In summary, when pleural effusions are detected by ultrasound, a detailed anatomic survey of the fetus should be performed and accompanied by a complete antenatal workup as recommended for fetuses with nonimmune hydrops. If no major anomalies or significant karyotypic abnormalities are documented and the effusions are detected before the third trimester, prenatal therapy should be considered. Finally, aggressive neonatal support is mandatory at the time of delivery

since there is no absolute way of determining before birth which babies will have a pulmonary function incompatible with life.

Antenatal diagnosis and management of monoamniotic twins

John F. Rodis, M.D., Anthony M. Vintzileos, M.D., Winston A. Campbell, M.D., Jeffrey L. Deaton, M.D., Fred Fumia, M.D., and David J. Nochimson, M.D.

Farmington, Connecticut

Double survival of monoamniotic twins is rare. Three consecutive cases in which double survival occurred are presented. Accurate antenatal diagnosis, intensive fetal surveillance, and operative delivery should improve neonatal outcome. (Am J Obstet Gynecol 1987;157:1255-7.)

Key words: Monoamniotic twins, antenatal diagnosis

The incidence of monozygotic twins is approximately one in 250 pregnancies, with little racial or geographic differences worldwide, as opposed to dizygotic twins. Only 1% to 2% of monozygotic twins are monoamniotic. The perinatal mortality rate of monoamniotic twins has been reported to be as high as 50%.[1, 2] We present three consecutive cases of monoamniotic twins with double survival in all and discuss the antenatal diagnosis and management.

Case reports

Case 1. A 22-year-old primigravida was transferred to the University of Connecticut Health Center at 33⅐ weeks' gestation because of preterm labor in a known twin gestation. Previous sonograms at 16, 20, and 24 weeks, as well as on adminssion, failed to reveal a dividing amniotic membrane. One placenta was seen, and amniotic fluid volume appeared normal around both female fetuses. No fetal anomalies were noted. At cesarean section both female fetuses occupied one amniotic sac. Twin B had a nuchal cord. The umbilical cords were intertwined and knotted and the placenta was monochorionic and monoamniotic (Fig. 1). Both

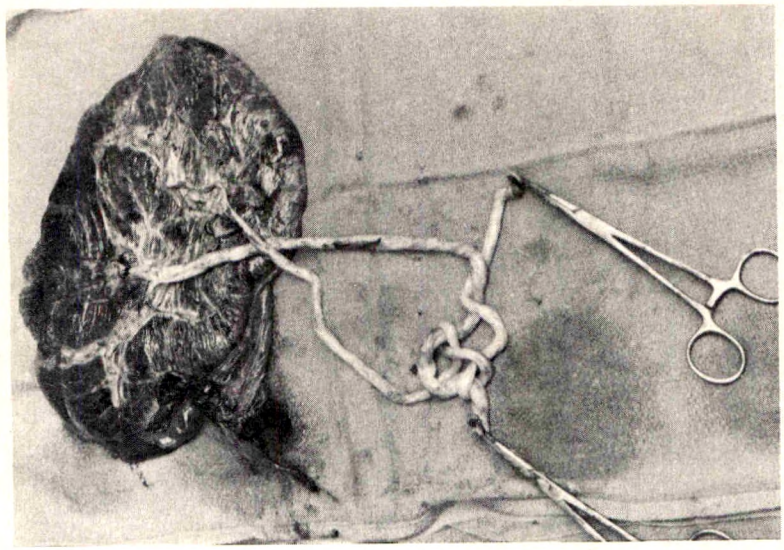

Fig. 1. Monochorionic, monoamniotic placenta with intertwining and knotting of cord.

fetuses and mother had uneventful postpartum courses and were discharged in good condition.

Case 2. A 28-year-old gravida 2, para 1 was discharged as having monoamniotic twins based on serial sonograms (one placenta, liked-sex female, absence of dividing membrane, and normal amniotic fluid around each fetus). Daily nonstress tests were begun at 27 weeks' gestation and were followed by biophysical profiles if nonreactive. At 34 weeks' gestation, a primary cesarean section was performed after confirmation of lung maturity by amniocentesis. Both twins were female, the cords were intertwined and knotted, and the placenta was monochorionic and monoamniotic. Mother and infants had unremarkable postpartum courses and were discharged on the fifth postpartum day.

Case 3. D. K. is a 36-year-old gravida 4, para 3 with known twin gestation. On ultrasound examinations performed at 14, 19, 20, and 24 weeks. a dividing membrane was never visualized while both female fetuses were surrounded by a normal amount of amniotic fluid. The patient was admitted to the University of Connecticut Health Center at 27 weeks' gestation for bed rest and daily fetal monitoring. Daily nonstress tests were performed on each fetus, and if nonreactive, were followed with biophysical profiles. Doppler umbilical artery velocimetry studies were performed every other day with an angioscan III. Ultrasound fetal measurements were obtained every 2 weeks to define the growth rate of each fetus and to look for signs of discordancy or twin-to-twin transfusion syndrome (ascites, pleural or pericardial effusions, and organomegaly). Betamethasone (12 mg intramuscularly) was administered weekly to enhance fetal pulmonary maturity.

Initial amniocentesis at 33 weeks revealed a lecithin/sphingomyelin ratio of 1.5 to 1. Repeat amniocentesis was performed at 34 weeks. Later that day occasional mild to moderate variable decelerations were noted on fetal heart rate monitoring. Before the result of the lecithin/sphingomyelin ratio was obtained, fetal bradycardia that was unresponsive to positional changes, intravenous fluids, and oxygen administration was noted in twin A. Immediate cesarean section was performed. At surgery only one amniotic sac was found. The umbilical cords were intertwined and knotted. Twin B had four loops of umbilical cord around the neck. Twin A, a 1720 gm female, had Apgar scores of 0 and 3 at 1 and 5 minutes, respectively, and required full cardiopulmonary resuscitation. Cord pH was 7.40 venous and 7.11 arterial. Twin B, a 1855 gm female, had Apgar scores of 1 and 7, at 1 and 5 minutes. Cord venous pH was 7.30 and arterial pH was 7.23.

Twin A was extubated on the first day of life and had an unremarkable neonatal course. Twin A had a hematocrit level of 45% at delivery and appeared to be the donor of a twin-to-twin transfusion syndrome. Twin B developed severe respiratory distress syndrome with classic radiographic findings and prolonged oxygen requirements. Twin B appeared to be the recipient of blood in the twin-to-twin transfusion syndrome with an initial hematocrit level of 61.7%. The lecithin/sphingomyelin ratio was subsequently reported as 2.7 to 1. Twin A was discharged from neonatal intensive care unit on the eleventh postnatal day and twin B on the fifty-sixth postnatal day. The mother had a benign postoperative.

Comment

If an original ultrasound examination fails to reveal a dividing amniotic membrane, a follow-up ultrasound examination should be performed at a tertiary care center. Before the diagnosis of monoamniotic twins can be entertained, the following criteria must be fulfilled:

(1) No dividing amniotic membrane should be visualized; (2) only one placenta should be seen; (3) both fetuses must have the same sex; (4) the fetuses must have adequate amniotic fluid surrounding them; and (5) both fetuses must move freely within the uterine cavity. This last point is important in avoiding the pitfall encountered in some diamniotic pregnancies in which the oligohydramnios in the one sac causes the membrane to be plastered against the fetus, thus making it difficult to visualize. This twin is usually flushed against the uterine wall, and this observation alone is indirect evidence of the presence of a dividing amniotic membrane. We recommend three consecutive ultrasound examinations to confirm the diagnosis.

Careful surveillance for the presence of fetal anomalies must be performed. Serial examinations every 2 weeks should be performed for assessment of fetal growth, discordancy, and twin-to-twin transfusion syndrome, which is a common problem in monoamniotic twins, and if significant may be a deciding factor for an earlier delivery. Cord entanglement should also be sought at each examination. We recommended hospitalization for bed rest and daily testing in all monoamniotic twins. Since the incidence of cord entanglement is great, we felt that changes in fetal heart tracings might precede intrauterine fetal demise as illustrated in case 2. Therefore daily nonstress tests are recommended.

With regard to the timing of the delivery, because of the rarity of the condition, no firm recommendations can be made based on data. However, since the perinatal mortality rate and incidence of cord entanglement are so high, we recommend intensive antenatal fetal surveillance from 25 until 32 weeks' gestation, after which time delivery should be undertaken. Amniocentesis may be helpful; however, even in the presence of a mature lung profile, one of the neonates may develop severe respiratory distress syndrome. If persistent variable decelerations or impaired fetal growth are noted, earlier delivery may be considered. We feel that cesarean section is the optimal route of delivery of monoamniotic twins. Unique complications of cord entanglement and the risk of fetal interlocking make vaginal delivery less than ideal.

In conclusion, monoamniotic twins represent a rare obstetric event with very high perinatal mortality. Accurate antenatal diagnosis, intensive antepartum fetal evaluation, and timed operative delivery in a tertiary care setting should improve the outcome of these infants.

Blood pressure in the midtrimester and future eclampsia

Leon C. Chesley, Ph.D., and Baha M. Sibai, M.D.
Memphis, Tennessee

The purpose of this report was to investigate the potential usefulness of average mean arterial pressure, maximal mean arterial pressure, and maximal diastolic pressure during the second trimester in predicting the development of eclampsia in 207 nulliparas and 20 multiparas with eclampsia. In the nulliparas, both the mean arterial pressure and the maximal mean arterial pressure during the second trimester were ≥90 mm Hg in 22% and 34% of the patients, respectively. For the multiparas, the percentages with ≥90 mm Hg were 30% and 35%, respectively. Only 8.7% of nulliparas with eclampsia had a maximal diastolic pressure during the second trimester ≥80 mm Hg and no patient had a diastolic pressure of ≥90 mm Hg. A review of the literature suggests that the mean arterial pressure observed during the second trimester has poor predictive value for future development of preeclampsia-eclampsia. We conclude that there is no correlation between second-trimester blood pressure recordings and subsequent eclampsia. (Am J Obstet Gynecol 1987;157:1258-61.)

Key words: Mean arterial pressure, eclampsia

Routine recordings of blood pressure, as ascertained by a variety of medical personnel, are usually the only data available for the evaluation of antepartum blood pressures in a busy obstetric service. No analysis of such data could be regarded as a scientific study of blood pressure, and yet they have some value. It has been alleged, for instance, that they are useful in the prediction of later preeclampsia.

Fallis and Langford[1] suggested that the level of blood pressure before the onset of toxemia might be predictive of the development of hypertension in late pregnancy. They studied 113 primigravidas, 95 of whom were black, and observed that the average mean arterial pressure had been 92.8 mm Hg in those patients who later developed toxemia and 83.0 mm Hg in those who did not (weighted averages derived from two sets of data in the paper).

Page and Christianson[2] averaged all the mean arterial pressures calculated from observations made during the second trimester for each of 14,833 women enrolled in the Kaiser-Permanente Foundation Health Plan in the San Francisco Bay Area and found that the later incidences of proteinuria, preeclampsia, and hypertension increased progressively with higher average mean arterial pressures during the second trimester, with sharp increments when the average mean arterial pressure was 95 mm Hg or higher. Among 686 women with an average mean arterial pressure during the second trimester of 95 mm Hg or higher, 5.4% developed proteinuria of at least two plus, 14.2% developed preeclampsia, and 25.9% had increases in mean arterial pressure to at least 110 mm Hg in the third trimester. The extent of overlapping of the three groups is unclear; presumably the women with proteinuria were included among the patients with preeclampsia, who may have been included among the women with hypertension.

Several such studies have purported to show that preeclampsia can often be predicted from average mean arterial pressure of the second trimester of 90 mm Hg or higher but with high percentages of false-positive and false-negative tests.[3-7] A basic weakness in such studies is that most of the diagnoses have been mild preeclampsia, a diagnosis that is erroneous in most multiparas and in a large proportion of primigravidas, many of whom have transient hypertension rather than preeclampsia.

The acid test of the efficacy of prediction is how well the mean arterial pressure of the second trimester foretells eclampsia. This article assesses the predictive value of blood pressure in the second trimester for the development of eclampsia in two large series, one during the period 1931 through 1951 and the other from 1977 through 1986. Relevant information is available for a total of 227 cases of eclampsia.

Material and methods

Cases of eclampsia that occurred in the Margaret Hague Maternity Hospital (1931 to 1952) in Jersey City, New Jersey, and the E. H. Crump Women's Hospital (1977 to 1986) in Memphis, Tennessee, were used for the retrospective analysis. Among the 303 cases at Mar-

Total	20	86.6 ± 8.0	30	5

garet Hague, recordings of blood pressures in the second trimester were available for only 85 nulliparas and nine multiparas. Among the 210 cases at E. H. Crump, recordings of blood pressures in the second trimester were available for 122 nulliparas and 11 multiparas. All patients with known chronic hypertension or renal disease were excluded from the analysis.

Mean arterial pressures were calculated by adding one third of the pulse pressure to the diastolic reading. For every patient, both average mean arterial pressure during the second trimester and maximal mean arterial pressure during the second trimester, as well as the maximal diastolic blood pressure in the second trimester were evaluated as predictors of future eclampsia. Results of various blood pressures studied were analyzed for each hospital and the two hospitals combined.

Results

Table I summarizes the average mean arterial pressure during the second trimester and the percentage of patients with levels ≥90 mm Hg in the two hospitals and the total number of patients with eclampsia for both nulliparas and multiparas. It is interesting to note that the findings in both groups are similar even though the patients were from two different regions at two different time periods. Overall, only 22% of nulliparas and 30% of multiparas had an average mean arterial pressure during the second trimester ≥90 mm Hg before the development of eclampsia. There were no immediate deaths from eclampsia at E. H. Crump, while five such deaths occurred at Margaret Hague. The average levels of mean arterial pressure during the second trimester in these deaths were 74, 83, 91, and 96 mm Hg in the nulliparas and 92 in the one multipara. Some of the multiparas in the Margaret Hague group may have had underlying and unrecognized chronic hypertension, since at follow-up seven of the eight surviving pregnant patients had chronic hypertension.

Table II summarizes the maximal mean arterial pressure in the second trimester and percentages of patients with levels ≥90 mm Hg in the two groups of patients. The findings in both groups are again almost identical. Overall, only 34% of nulliparas and 35% of multiparas had a maximum mean arterial pressure during the second trimester ≥90 mm Hg, an incidence that is slightly lower than the 39% found in whole hospital populations by Friedman and Neff.

Table III shows the maximal diastolic pressure during the second trimester in both groups of patients with eclampsia. There were no differences between patients from the different hospitals and between nulliparas and multiparas. It is apparent that the maximal diastolic pressure during the second trimester has the worst predictive value regarding future development of eclamp-

Table III. Maximal diastolic pressure in the second trimester in two groups of patients with eclampsia

Group	No. of cases	Mean ± 1 SD	% with		
			80-84	85-89	90-94 mm Hg
Nulliparas					
Margaret Hague	85	71.7 ± 9.8	6	3	0
E. H. Crump	122	71.4 ± 8.0	7	2	0
Total	207	71.5 ± 9.0	6.3	2.4	0
Multiparas					
Margaret Hague	9	71.6 ± 9.0	22	0	11
E. H. Crump	11	72.9 ± 9.1	18	9	0
Total	20	72.2 ± 9.1	20	5	5

sia. Overall, only 8.2% of nulliparas had a maximal diastolic pressure during the second trimester ≥80 mm Hg, and no patient in this group had a level >90 mm Hg. In the multiparas, 30% of patients had a maximal diastolic pressure ≥80 mm Hg, but only 5% had a level of ≥90 mm Hg. This finding may reflect the fact that some of the multiparas may have had underlying and unrecognized chronic hypertension.

Comments

The findings of this study reveal that only 22% of 207 nulliparas with eclampsia have an average mean arterial pressure during the second trimester ≥90 mm Hg, whereas 30% of 20 multiparas with eclampsia have had such a finding. It seems that an average mean arterial pressure during the second trimester ≥90 mm Hg is not sensitive enough to predict the future development of eclampsia. The same holds true for a maximal mean arterial pressure value of ≥90 mm Hg, since only 34% of nulliparas with eclampsia and 35% of multiparas with eclampsia had such a value. As for the maximal diastolic pressure recording in the second trimester, this test appears to be the poorest for the future development of eclampsia in the nulliparas. In fact, only 8.7% of nulliparas with eclampsia had a value of ≥80 mm Hg, and no patient had a diastolic pressure of ≥90 mm Hg in the second trimester. On the other hand, 30% of multiparas with eclampsia had a maximal diastolic pressure during the second trimester ≥80 mm Hg. This finding may reflect the fact that some of these patients might have had underlying and unrecognized chronic hypertension.

Moller and Lindmark[8] reported on 74 patients who developed eclampsia in Sweden during the years 1967 to 1980. Only five patients did not have regular prenatal care visits, and 88% had their first prenatal visit before 16 weeks' gestation. The average blood pressure in these patients at initial visit was 120/70 mm Hg. Thirty-three patients had eclampsia before 37 weeks' gestation and 41 had eclampsia at ≥37 weeks. The authors found that only 39% of patients who had eclampsia before 37 weeks and 16% of patients who had eclampsia beyond 37 weeks' gestation had a diagnosed elevation of blood pressure (≥140/90 mm Hg) 4 days before the first eclamptic convulsion. It can be concluded from these findings that most patients wtih eclampsia had a maximal diastolic pressure of <90 mm Hg before the onset of eclampsia. In addition, several of these women had an average mean arterial pressure during the second trimester of <90 mm Hg.

The onset of eclampsia may be abrupt without any warning signs or symptoms in about 20% of cases. In studying the possible factors leading to the development of eclampsia in 66 patients, Campbell and Templeton[9] found that the onset was abrupt in 11 patients (16.7%). These patients had normal blood pressure and absent proteinuria within 1 week before the onset of convulsions. In addition, Dieckmann[10] found that 22% of patients with eclampsia had a systolic blood pressure <140 mm Hg before the onset of convulsions. Recently Clark et al.[11] compared the hemodynamic findings in three patients with eclampsia and four patients with severe preeclampsia. They found similar hemodynamic findings in the two groups except for a significantly lower plasma colloid osmotic pressures in the patients with eclampsia. This suggests that eclampsia is a multifactorial disease and that current techniques to predict subsequent eclampsia are indeed lacking.

In summary, the level of the mean arterial blood pressure during the second trimester is a poor predictor for the future development of eclampsia and might give the clinician a false sense of security when it is negative (<90 mm Hg). We believe that if an increase in the levels of mean arterial pressure during the second trimester predict anything, it is transient hypertension rather than eclampsia.

Hypoxia-induced fetoplacental vasoconstriction in perfused human placental cotyledons

Randy B. Howard, Ph.D., Tomokazu Hosokawa, Ph.D., and M. Helen Maguire, Ph.D.
Kansas City, Kansas

Effects of maternal hypoxia on fetoplacental vascular resistance in the human placenta were investigated in an in vitro model in which single anatomic subunits (cotyledons) from term placentas were perfused at constant flow through both fetal and maternal circuits by means of a physiologic salt solution containing dextran. Acute reduction of oxygen tension in the maternal perfusate induced prompt fetoplacental vasoconstriction that recovered rapidly on restoration of oxygen to the perfusate. The response, hypoxic fetoplacental vasoconstriction, could be repeatedly demonstrated in the same cotyledon. The time course of hypoxic fetoplacental vasoconstriction was inversely related to oxygen tension of maternal arterial and maternal and fetal venous perfusates. Maternal and fetal venous perfusate pH and P_{CO_2} did not change during the response. It is concluded that hypoxic fetoplacental vasoconstriction is triggered by decreased oxygen availability. It is suggested that hypoxic fetoplacental vasoconstriction may play a role in local regulation of human fetoplacental blood flow in vivo and may contribute to poor fetal prognosis in preeclampsia. (AM J OBSTET GYNECOL 1987;157:1261-6.)

Key words: Hypoxia, fetoplacental vasoconstriction, placental perfusion

A major function of the placenta is the transfer of oxygen and nutrients from maternal to fetal blood. Regulation of fetal blood flow through the placenta is not understood, but since fetoplacental vessels are not innervated, local and/or humoral mechanisms are likely to be important. In the near-term sheep, occlusion of maternal placental blood flow reduced adjacent fetal placental flow,[1] and similarly ligation of a portion of the umbilical vasculature resulted in a decrease in adjacent maternal placental flow,[2] which support the concept of local regulatory interaction between fetal and maternal placental circulations in this species.[1] The ovine placenta is epitheliochorial and differs from the hemochorial human placenta in anatomic separation of maternal and fetal blood. Whether fetoplacental blood flow in human pregnancy is influenced by uteroplacental blood flow is not known. Demonstration of such an interaction in the human placenta would have potential significance in understanding how fetoplacental vascular resistance is controlled in normal pregnancy and in preeclampsia, a common disorder of pregnancy.

Preeclampsia is typically associated with placental ischemia,[3] and chronic hypoxia has been suggested as a factor contributing to the narrowing and obliteration of fetal arteries observed in placentas from patients with preeclampsia.[4] In the present study we asked whether uteroplacental hypoxia might affect human fetoplacental vascular resistance and thus modify fetal blood flow through the placenta.

Effects of human placental hypoxia could not be determined in vivo because studies of placental function in vivo are limited to therapeutic and noninvasive procedures. Moreover, we did not have access to an animal model of the villous hemochorial placenta, such as the subhuman primate. We therefore used an in vitro model, the isolated dual-perfused cotyledon from human term placenta.[5] The human placenta is made up of a number of discrete anatomic subunits or cotyledons that can be isolated and perfused via both fetal and maternal circuits.[5] Maternal circulation in the human placenta is not confined to a separate vasculature but flows into the intervillous space and directly bathes the villi of the fetal placenta. In the placental model perfused in vitro, cannulas inserted through the maternal surface of the cotyledon deliver perfusate to the intervillous space[5]: Careful placement of the cannulas is necessary to achieve adequate perfusion of the intervillous space. Using this preparation, we have determined dose-dependent effects of autacoids and humoral agents on fetoplacental vascular resistance.[6-8] In this article we report that perfusion of the maternal circuit of the in vitro placental cotyledon with hypoxic medium causes reversible fetoplacental vasoconstriction.

Material and methods

Placentas from normal full-term pregnancies were obtained immediately after delivery. A single cotyledon from each placenta was set up for constant flow perfusion of the fetal circuit and intervillous space with Earle's salt solution to which 40 gm/L of dextran (approximate molecular weight 40,000) was added.[5-7] The upper chamber of the perfusion apparatus was open to allow access to the maternal surface of the perfused cotyledon. Preparation and perfusates were maintained at 37° C. Perfusate flow rates were monitored with Gilson No. 1 flowmeters. Fetal perfusate was gassed with 94% nitrogen, 6% carbon dioxide. Normoxic maternal perfusate was gassed with 95% oxygen, 5% carbon dioxide, and hypoxic maternal perfusate was gassed with 95% nitrogen, 5% carbon dioxide in a separate reservoir. Effective placement of maternal cannulas was monitored by measurement of fetal venous gas tensions and pH. Maternal flow rate was increased, if necessary, to achieve fetal venous pH of 7.30 to 7.35, P_{CO_2} of 39 to 47 mm Hg, and P_{O_2} >100 mm Hg. Gas and pH values of perfusates were measured with a Radiometer BMS 3 blood gas analyzer. Maternal and fetal arterial and venous perfusates were sampled with glass syringes from ports in the perfusion lines. Maternal venous perfusate was sampled by a syringe from the perfusate outflow above the maternal surface adjacent to the maternal cannulas. Perfusion pressures were monitored via Statham P23ID transducers and recorded on a Gilson ICT-2H duograph; perfusion pressure of the fetal circuit was used as an index of fetal vascular resistance.

Experimental procedure. Control conditions of normoxic maternal perfusion were established. Hypoxia was then imposed by substitution of the normoxic maternal perfusate by hypoxic maternal perfusate for 8 to 15 minutes; perfusion with normoxic maternal perfusate was then reinstituted. Transit time from reservoir to intervillous space was 1 to 2 minutes. A period of 3 to 4 minutes was allowed to elapse between recovery and the next hypoxic challenge of the same duration. At the end of each experiment, a 1% solution of Coomassie blue in saline solution was infused via the fetal arterial cannula, and the cotyledon demarcated by the dye was dissected and weighed. Perfusate flow rates are expressed as ml min^{-1} gm^{-1}.

Perfusion medium. Earle's salt solution had the following composition (mmol/L): NaCl 116.4; $NaHCO_3$ 26.2; KCl 5.36; $CaCl_2$ 1.80; $MgSO_4$ 0.81; NaH_2PO_4 1.01; and glucose 5.5. NaCl was Fisher biologic grade. Other salts were the best analytic grade available. Dextran, molecular weight 38,000 to 42,000, was obtained from Chemical Dynamics Corp., New Jersey, or ICN, Ohio.

Data analysis. Results are given as mean ± standard error of the mean. Differences between means of perfusate gas and pH values before and during maternal hypoxia were evaluated by a one-way analysis of variance F test with 4 and 15 degrees of freedom; BMDP7D[9] statistical software was used for computations. Correlation coefficients, partial correlation coefficients,[10] and multiple-regression analysis were computed with BMDP6R and BMDP2R statistical software.[9]

Results

Weights of the 44 cotyledons used in the study ranged from 8 to 27 gm with a mean of 14.8 ± 0.7 gm. Control fetal vascular resistance in the preparations was 115 ± 6 mm Hg min gm ml^{-1}, and mean flow rates of maternal and fetal perfusates were 1.35 ± 0.005 and 0.41 ± 0.02 ml min^{-1} gm^{-1}, respectively. Perfusates had the following control gas and pH values: maternal arterial: pH 7.393 ± 0.003, P_{CO_2} 34.8 ± 0.3 mm Hg, P_{O_2} 540 ± 4 mm Hg (n = 16 to 18 cotyledons); maternal venous: pH 7.358 ± 0.007, P_{CO_2} 40.6 ± 0.4 mm Hg, P_{O_2} 355 ± 14 mm Hg (n = 11 to 14 cotyledons); fetal arterial: pH 7.342 ± 0.007, P_{CO_2} 42.9 ± 0.6 mm Hg, P_{O_2} 27 ± 2 mm Hg (n = six cotyledons); and fetal venous: pH 7.357 ± 0.003, P_{CO_2} 42.6 ± 0.4

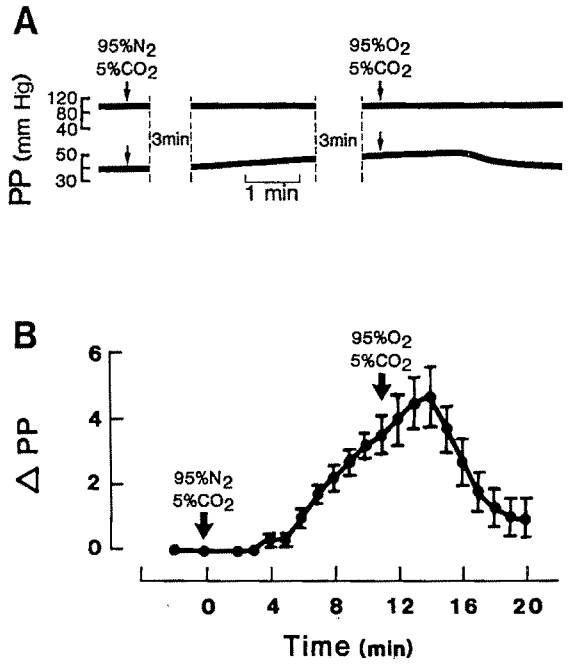

Fig. 1. A, Typical effects on maternal *(upper tracing)* and fetal *(lower tracing)* perfusion pressure observed when the maternal circuit of the human placental cotyledon was perfused with hypoxic medium. *Arrows* indicate the start of 9 minutes of hypoxic maternal perfusion (95% N_2, 5% CO_2) and restoration of normoxic perfusion (95% O_2, 5% CO_2). **B,** Time course of averaged pressor responses to three sequential hypoxic stimuli of 10-minute duration in one cotyledon. (Δ *PP* = Change in perfusion pressure [mm Hg], *bars* indicate standard error of the mean.)

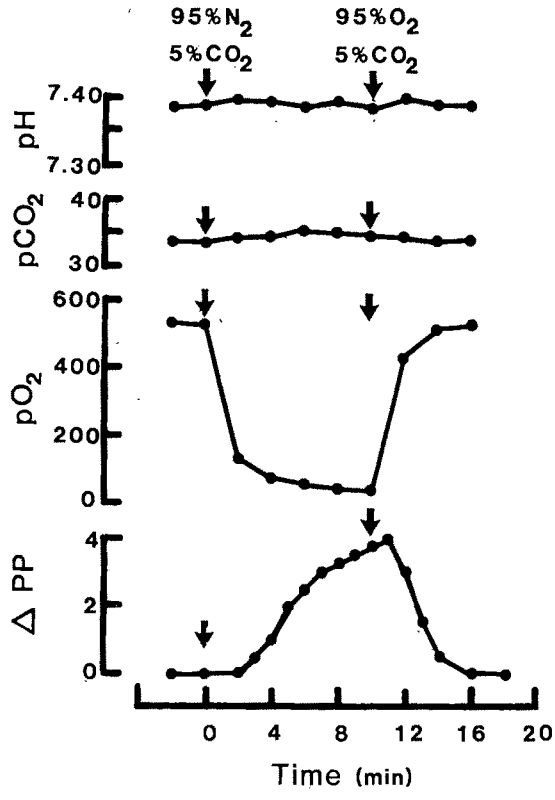

Fig. 2. Time courses of a typical fetal pressor response and associated maternal arterial perfusate gas and pH values induced by 10-minute hypoxic challenge in a single cotyledon. *Arrows* indicate start of hypoxic maternal perfusion (95% N_2, 5% CO_2) and normoxic maternal perfusion (95% O_2, 5% CO_2). (Δ *PP* = Change in fetal perfusion pressure [mm Hg].)

mm Hg, Po_2 198 ± 5 mm Hg (n = 42 cotyledons). The mean arteriovenous increase in fetal perfusate Po_2 of approximately 170 mm Hg indicated that a significant fraction of oxygen entering the maternal side of the cotyledon was transferred across the placenta.

Perfusion of the maternal circuit of the cotyledons with hypoxic perfusate induced prompt reversible vasoconstriction of the fetoplacental vasculature as evidenced by a rise in fetal perfusion pressure 2 to 4 minutes after perfusion with the hypoxic perfusate commenced, which was followed by a drop in pressure 2 to 4 minutes after delivery of normoxic maternal perfusate was reinstituted (Fig. 1, *A*). Fetoplacental vasoconstriction induced by maternal hypoxia could be repeatedly elicited in the same cotyledon (Fig. 1, *B*). Return to baseline perfusion pressure was complete or nearly complete with recovery from each response (Figs. 1, *B*, 2, and 3). This reversible response is described as hypoxic fetoplacental vasoconstriction.

Development of the fetal pressor response to maternal hypoxia and recovery of baseline perfusion pressure paralleled changes in the oxygen tension of maternal and fetal perfusates. Fig. 2 shows the fall in maternal arterial Po_2 from 540 to 25 mm Hg that accompanies the onset of hypoxic fetoplacental vasoconstriction and the subsequent return to control level Po_2 associated with recovery from the response. The onset of hypoxic fetoplacental vasoconstriction and recovery from hypoxic fetoplacental vasoconstriction were also reflected in the fall and rise, respectively, of Po_2 in both maternal and fetal venous perfusates as shown for a typical experiment in Fig. 3. Oxygen tensions in both maternal and fetal venous perfusates varied significantly during hypoxic fetoplacental vasoconstriction (fetal venous $F = 490.48$, $p < 0.0001$; maternal venous $F = 70.85$, $p < 0.0001$). As indicated in Fig. 3, the pressor response commenced as the fetal venous Po_2 fell below approximately 100 mm Hg and continued to rise as fetal venous Po_2 fell to below 40 to 50 mm Hg 2 to 4 minutes after reinstitution of normoxic perfusion. No significant change from prehypoxic maternal venous or fetal venous pH was observed during hypoxic fetoplacental vasoconstriction (compare Fig. 3; fetal venous, $F = 0.12$, $p = 0.97$; maternal venous, $F = 0.47$, $p = 0.76$). No significant change from prehypoxic values occurred in either fetal venous

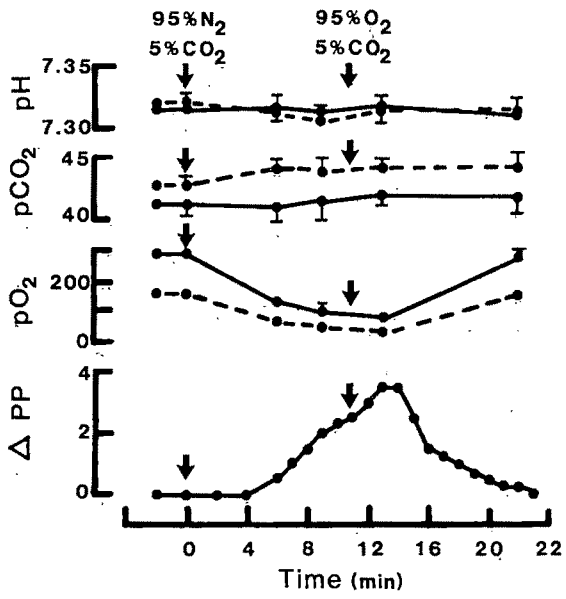

Fig. 3. Time courses of fetal *(broken lines)* and maternal *(solid lines)* venous perfusate gas and pH values induced by three hypoxic stimuli of 11-minute duration and a typical pressor response in the same cotyledon. *Arrows* indicate start of maternal hypoxic (95% N_2, 5% CO_2) and maternal normoxic (95% O_2, 5% CO_2) perfusion. Gas and pH values are mean ± standard error of the mean; where not shown standard error of the mean is within the data point. (Δ *PP* = Change in perfusion pressure [mm Hg].)

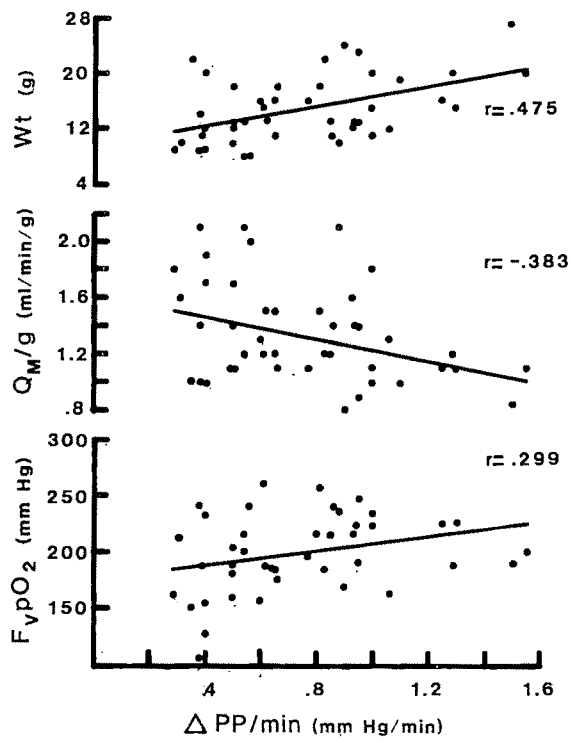

Fig. 4. Relationships between the normalized fetal pressor response to hypoxic challenge (Δ PP min^{-1}, mm Hg min^{-1}) and each of three different parameters of perfusion: cotyledon weight *(wt)*, maternal flow per gm (Q_M gm^{-1}, ml min^{-1} gm^{-1}), and control (i.e., before hypoxic challenge) fetal venous P_{O_2} ($F_vP_{O_2}$) in 41 different cotyledons. (*r* = simple correlation coefficient.)

P_{CO_2} or maternal venous P_{CO_2} during the response (fetal venous F 0.25, p = 0.90; maternal venous F = 0.28, p = 0.89) (Fig. 3). Furthermore, in two preparations subjected to repeated hypoxia, neither P_{CO_2} nor pH of fetal venous perfusate measured before hypoxic vasoconstriction differed significantly from pH and P_{CO_2} measured during peak hypoxic vasoconstriction within each preparation (Table I). However, fetal venous P_{O_2} during hypoxic constriction fell to less than 25% of the prehypoxia control level (Table I). Similarly, comparison of gas tensions and pH values of maternal venous perfusates before and during repeated hypoxic fetoplacental vasoconstriction in three different cotyledons showed no difference in pH and P_{CO_2} before and during the responses but showed a twofold to threefold fall in P_{O_2} (data not shown).

In 55% of the cotyledons studied, the maximum extent of vasoconstriction to hypoxic stimuli of 9- to 11-minute duration was observed with the first hypoxic stimulus, but in 45% of the cotyledons the magnitude of the response increased with repeated hypoxia until the maximum response observed in the cotyledon was achieved with the third or fourth stimulus. The reason for this difference between cotyledons is not presently understood. The maximum hypoxic vasoconstriction for each cotyledon, which was normalized as pressure increase per minute of hypoxic stimulus, ranged from 0.3 to 1.6 mm Hg min^{-1}, with a mean of 0.76 ± 0.05 mm Hg min^{-1} (n = 44 cotyledons). It was thought that the variation between cotyledons in the normalized response to maternal hypoxia might be related to parameters of the preparation such as cotyledon weight, maternal and fetal flow rates (ml min^{-1} gm^{-1}), control fetoplacental vascular resistance (mm Hg min gm ml^{-1}), or control perfusate gas tensions and pH. Regression analysis showed that the normalized hypoxic pressor response indeed correlated with cotyledon weight, maternal flow rate, and control (normoxic) fetal venous P_{O_2}, as shown in Fig. 4 and by the simple correlation coefficients given in the figure. However, the response did not correlate with fetal venous pH (r = 0.047), fetal venous P_{CO_2} (r = 0.09), fetal perfusate flow rate (r = 0.141), or fetoplacental vascular resistance (r = 0.036). Further statistical analysis was performed to elucidate how the normalized hypoxic pressor response was related to cotyledon weight, maternal flow rate, and normoxic fetal venous P_{O_2}. Specifically, partial correlation coefficients were computed to assess the extent to which each of these three parameters were (uniquely)

Table I. Comparison of fetal venous perfusate pH, P_{CO_2}, and P_{O_2} during normoxic maternal perfusion before hypoxic challenge with pH, P_{CO_2}, and P_{O_2} at the peak pressor response to hypoxic maternal perfusion in two dual-perfused placental cotyledons

Cotyledon No.	*Duration of hypoxia (min)*	*n**	*Fetal venous pH*		*Fetal venous P_{CO_2}*		*Fetal venous P_{O_2}*	
			Control	*Hypoxia*	*Control*	*Hypoxia*	*Control*	*Hypoxia*
1	10	7	7.372 ± 0.001	7.373 ± 0.001	41.3 ± 0.3	41.3 ± 0.2	196 ± 2	47 ± 3
2	11	4	7.320 ± 0.005	7.316 ± 0.01	43.1 ± 0.7	44.2 ± 1.0	155 ± 2	31 ± 2

Values are mean ± SEM.

*Number of sequential hypoxic stimuli; replicate three to five measurements of pH, P_{CO_2}, and P_{O_2} were made in control and hypoxia perfusates sampled before and during each pressor response.

related to the pressor response while statistically controlling the influences of the other two. Partial correlation coefficients of the pressor response with fetal venous P_{O_2}, cotyledon weight, and maternal flow rate (ml min^{-1} gm^{-1}) were 0.449, 0.325, and −0.087, respectively, thus suggesting that control fetal venous P_{O_2} was the parameter most highly related to the normalized pressor response independent of the other two parameters. However, the partial correlation coefficient of 0.325 associated with cotyledon weight suggests that it too may be uniquely related to the magnitude of the normalized hypoxic pressor response. These conclusions were confirmed by multiple-regression analysis for the normalized pressor response ($R = 0.6035$). Of the three individual regression coefficients, those for fetal venous P_{O_2} ($p < 0.01$) and cotyledon weight ($p < 0.05$) were statistically significant.

Comment

In this study the effect of acute uteroplacental hypoxia on human fetoplacental vascular resistance has been investigated with the isolated dual-perfused placental cotyledon as an in vitro experimental model. Several parameters of this in vitro model resembled those reported for the in vivo placenta. Specifically, maternal and fetal flow rates of 1.35 ± 0.005 and 0.41 ± 0.02 ml min^{-1} gm^{-1} were similar to flow rates calculated for maternal and umbilical blood in vivo, that is, 1.0 and 0.6 ml min^{-1} gm^{-1}, respectively (calculated using reported uteroplacental[11] and umbilical[12] flow rates and assuming a placental weight of 500 gm), and gas tensions and pH of the fetal arterial perfusate approximated those found in vivo.[13] With this model we demonstrated that maternal hypoxia induced reversible fetoplacental vasoconstriction. The response was inversely related to maternal arterial perfusate oxygen tension and was associated with a reversible drop in P_{O_2} of maternal and fetal venous perfusates. However, neither pH nor P_{CO_2} of the venous perfusates changed during the hypoxic response, which suggests that the mechanism of the response does not involve change in glucose metabolism. We conclude that decreased oxygen availability is the primary triggering factor in hypoxic fetoplacental vasoconstriction since oxygen tension was the only variable changed.

A fivefold variation in the size of the normalized hypoxic vasoconstriction between different cotyledons was observed and was shown by statistical analysis to be correlated with two prestimulus perfusion parameters, control fetal venous P_{O_2} and cotyledon weight. These findings suggest that cotyledons that transferred oxygen most effectively across the placenta and larger cotyledons were more sensitive to maternal hypoxia. Reasons for the increased sensitivity are unknown. However, it may be speculated that general function was better preserved in those cotyledons that transferred oxygen to the fetal circulation more effectively, and that as a result sensitivity to lack of oxygen was greater. On the other hand, the basis of the positive correlation between cotyledon size and sensitivity to maternal hypoxia is less readily explained. It is unlikely to be the result of better maternal perfusion in the larger cotyledons, since analysis of interrelationships of perfusion parameters under control conditions has shown that maternal flow rate (ml min^{-1} gm^{-1}) correlated negatively with cotyledon weight.[14] Again, it may be that function is better preserved at term in the larger cotyledons.

Although we have demonstrated hypoxic fetoplacental vasoconstriction in an artificially perfused placental preparation in vitro, the response could be important in vivo, for example, in acute local blood flow regulation in which it may result in a redistribution of fetoplacental blood flow from hypoxic to normoxic or better perfused regions of the placenta. In this regard, the response may be analogous to the phenomenon of hypoxic pulmonary vasoconstriction, which is important in the adjustment of ventilation-perfusion ratios in the lung. We have shown that verapamil and lipoxygenase inhibitors antagonize hypoxic fetoplacental vasoconstriction,[15] which suggests that the response is mediated, at least in part, by release of lipoxygenase products.

Fetoplacental vasoconstriction in response to maternal hypoxia has not been previously described, although it is reminiscent of the reduction of fetal placental blood flow observed 24 hours after maternal placental occlusion in the near-term sheep.[1] However, we know of no evidence that the ovine response to occlusion of maternal placental flow occurs acutely and reversibly. An acute pressor response to abolition of maternal perfusion can be demonstrated in the in vitro placental preparation and is reversible on restoration of maternal perfusion.[16]

Hypoxic fetoplacental vasoconstriction in the in vitro cotyledon resulted from acute change in maternal oxygen tension. It seems possible that in vivo, chronic placental hypoxia such as has been postulated to occur in preeclampsia[3, 4] may cause a chronic vasoconstrictor response that may contribute to fetal mortality and growth retardation associated with this disease. Furthermore, release of hypoxia-induced vasoconstrictive mediators may be important in the etiology of preeclampsia.

We thank Dr. C. R. King and the staff of the delivery room of Bell Memorial Hospital for their help in obtaining the placentas, and Dr. J. Levy for performing data analysis.

Haptoglobin helps diagnose the HELLP syndrome

Peeter A. Poldre, M.D.
Toronto, Ontario, Canada

In a case of the HELLP syndrome, anemia was absent, and bilirubin and lactic dehydrogenase levels were normal. In combination with minimal microangiopathic changes in red cell morphology, a decrease in serum haptoglobin was useful to corroborate the presence of intravascular hemolysis. (AM J OBSTET GYNECOL 1987;157:1267.)

Key words: HELLP syndrome, serum haptoglobin level

The HELLP syndrome (hemolysis, elevated liver function tests, and low platelets) has become a recognized cause of antenatal thrombocytopenia.[1] Diagnostic uncertainty may arise if one component of the classic triad seems to be absent. This report illustrates a case of the HELLP syndrome in which a decrease in serum haptoglobin level confirmed the presence of hemolysis despite normal hemoglobin, bilirubin, and lactic dehydrogenase levels.

Case report

A 29-year-old primigravida in her thirty-seventh week of gestation came to the hospital with a 5-hour history of right upper quadrant pain. Blood pressure was 124/70 mm Hg. Her diastolic pressure had previously never exceeded 60 mm Hg. There was no peripheral edema. Laboratory investigations included: hemoglobin, 125 gm/L (normal, 120 to 160 gm/L); platelet count, 73×10^9/L (normal, 150 to 450 $\times$ 10^9/L); and normal values for white blood count, prothrombin time, activated partial thromboplastin time, and fibrinogen. Abnormal hepatic function tests included alkaline phosphatase, 200 U/L (normal, 25 to 100 U/L); alanine aminotransferase, 407 U/L (normal, 10 to 45 U/L); and aspartate aminotransferase, 296 U/L (normal 7 to 40 U/L). Serum bilirubin and lactic dehydrogenase levels were normal. A 24-hour collection of urine did not reveal proteinuria.

Red cell morphology was microscopically assessed in 30 high-power ($\times$ 1000) fields, and 1.3 schistocytes were noted per field. In five nonanemic, predelivery subjects assessed in the same laboratory, schistocyte counts averaged 0.3 per high-powered field. Serum haptoglobin level was found to be depressed at 0.6 gm/L (lower limit of normal 1.0 gm/L).

Within 2 days of admission, spontaneous delivery occurred. Normalization of the patient's platelet count occurred in 2 days and correction of the hepatic function test abnormalities and the serum haptoglobin was documented three weeks postpartum.

Comment

In Weinstein's[1] update of his experience with the HELLP syndrome, 48 of 56 patients had abnormal peripheral blood films, including the presence of burr cells and/or schistocytes. Sibai et al.[2] reviewed 112 patients, and all were found to have abnormal peripheral smears and lactic dehydrogenase levels above 600 IU/L. Neither commented on the degree of morphologic changes in the blood films of their patients, and Weinstein did not comment on evidence of hemolysis in the eight patients who had a normal peripheral film.

Our patient was not anemic and did not have an elevated bilirubin or lactic dehydrogenase level but had modest morphologic evidence of microangiopathic hemolysis. To corroborate the occurrence of intravascular hemolysis, the serum haptoglobin was assayed and found to be decreased. Haptoglobin is an α_2-plasma protein that binds to free hemoglobin and forms a complex that is removed by the reticuloendothelial system. A low level of haptoglobin is a sensitive indicator of intravascular red cell destruction. In this case, the lowered serum haptoglobin level was valuable in confirming the presence of hemolysis despite the absence of anemia, hyperbilirubinemia, or elevated lactic dehydrogenase levels.

In conclusion, in suspected cases of the HELLP syndrome in which evidence of hemolytic anemia is absent or modest, assay of the serum haptoglobin may assist in the diagnosis.

We thank Drs. D. Steele and C. Norman for reviewing the patient and the red cell morphology, and R. Yano for manuscript preparation.

Insufficient transplacental digoxin transfer in severe hydrops fetalis

Johnny S. Younis, B.M.Sc., M.D., and Menachem Granat, M.D.
Jerusalem, Israel

A case of severe nonimmune hydrops fetalis caused by supraventricular tachycardia is presented. Maternal treatment with digoxin and the subsequent addition of verapamil and propranolol failed to be effective. Simultaneous measurement of maternal serum and cord blood digoxin levels showed insufficient transplacental digoxin transfer. Other modalities of treatment are discussed. (Am J Obstet Gynecol 1987;157:1268-9.)

Key words: Nonimmune hydrops fetalis, supraventricular tachycardia, digoxin treatment

It has been suggested that aggressive transplacental therapy of fetal supraventricular tachycardia would be preferable to premature termination of pregnancy and subsequent extrauterine therapy, especially when the arrhythmia is associated with cardiac compromise and hydrops fetalis.[1]

Maternal digoxin administration remains the treatment of first choice in these cases, with the goal of attaining a maternal digoxin level at the upper end of the therapeutic range. It has been reported that the cord blood digoxin level in nonhydropic fetuses at labor was similar to the maternal level at birth in patients with cardiac disease treated with digoxin.[2]

Case report

We recently encountered a 34-year-old woman, gravida 4, para 2, in the twenty-seventh week of gestation whose fetus was severely hydropic as a result of supraventricular tachycardia of 260 bpm. A complete search for other causes of nonimmune hydrops fetalis was negative. Ultrasonic examination showed scalp edema, severe ascitis, severe pleural effusion, pericardial effusion, placentomegaly with a maximal thickness of 75 mm, and severe oligohydramnios. Echocardiography of the fetal heart anatomy was normal, and supraventricular tachycardia was clearly verified. Treatment was initiated with maternal digoxin administration (a loading dose of 1.25 mg by mouth and a maintenance dose of 0.425 to 0.5 mg/dl) with the subsequent addition of verapamil and propranolol, but sinus rhythm was not restored and the hydrops deteriorated. Maternal digoxin serum levels, which were measured by radioimmunoassay, were 1.1 to 1.9 ng/ml. Three weeks after the initiation of antiarrhythmic therapy, fetal membranes ruptured spontaneously and abruption of the placenta was diagnosed. A cesarean section was immediately performed, and a severely hydropic male fetus weighing 2175 gm was delivered. The placenta weighed 1350 gm and was extremely edematous. At operation the maternal ovaries were noted to be edematous and polycystic. Sinus rhythm (140 bpm) was restored spontaneously after the umbilical cord was clamped. The newborn infant was resuscitated and mechanically ventilated but after 3 days died of severe respiratory insufficiency. Simultaneous measurements of maternal and cord blood, ovarian follicular fluid, and fetal ascitic fluid for digoxin levels are shown in Table I. These figures indicate insufficient transplacental digoxin transport.

Table I. Digoxin levels in the biologic fluids of the treated mother and fetus with hydrops fetalis

	Biologic fluid	*Digoxin levels (ng/ml)*
Maternal	Serum	1.1
	Ovarian follicular fluid	1.1
Fetal	Cord blood serum	0.3
	Ascitic fluid	0.3

Comment

It seems that the apparent passive transfer of digoxin across the placenta in normal fetuses[2] was probably disturbed in our patient by the high intravascular hydrostatic pressure existing in cases of hydrops fetalis. As in other cases reported in the literature, treatment failure may also be the result of severe placental edema and increased maternofetal diffusion distance.

The prognosis of prematurely delivered fetuses with hydrops is very unfavorable.[1] Therefore in cases of severe hydrops resulting from fetal arrhythmia with associated extreme edema of the placenta that do not respond to maternal administration of antiarrhythmic

drugs, other therapeutic measures should be considered. An attempt may be made to reverse the arrhythmia by compression of the umbilical cord, or else the drug may be injected directly into the umbilical cord or the fetal gluteus muscle by means of ultrasonic guidance. The possibility of maternal administration of an antiarrhythmic drug that actively cross the placenta, such as procainamide, may also be considered.

Renal arterial blood flow velocity waveforms in pregnant women

Toshiyuki Hata, M.D., Kohkichi Hata, M.D., Showa Aoki, M.D., Osamu Takamiya, M.D., Fuminori Murao, M.D., and Manabu Kitao, M.D.

Izumo, Japan

Seventy-two continuous-wave Doppler ultrasonographic examinations were performed on nine nonpregnant and 56 normal pregnant women. The range of gestation was 6 to 40 weeks, and the objective was to record the renal arterial blood flow velocity waveform. Acceleration time and systolic per diastolic ratio of renal arterial blood flow velocity waveforms were assessed. Of 72 examinations, 68 recordings were made of the left renal artery (94.4%) and 28 of the right renal artery (38.9%), respectively. There was no correlation between acceleration time and systolic per diastolic ratio and gestational age, respectively, and no correlation between acceleration time and systolic per diastolic ratio, and caliceal diameter of the renal pelvis, respectively. Acceleration times of the left and right renal arteries were 47 ± 11 and 40 ± 8 msec in nonpregnant women and 62 ± 23 and 62 ± 23 msec in pregnant women, respectively. The left and right systolic per diastolic ratios were 3.1 ± 0.7 and 2.9 ± 0.5 in nonpregnant women and 2.8 ± 0.6 and 2.6 ± 0.5 in pregnant women, respectively. Therefore these data provide a foundation for the study of hydronephrosis, which may occur in pregnant women. (Am J Obstet Gynecol 1987;157:1269-71.)

Key words: Doppler ultrasound, renal artery, hydronephrosis, pregnancy

Ultrasonographic assessments of asymptomatic maternal hydronephrosis in pregnancy have been reported.[1-4] Regression occurred gradually after delivery.[5] There are at least two theories regarding the etiology, namely, hormonal effect and mechanical compression.[6]

With recent advances in Doppler ultrasound examination, measurements of renal arterial blood flow velocity waveforms have been made to predict renal function and damage in normal, abnormal, and allografted kidneys.[7-9] To the best of our knowledge, there has been no documentation of maternal renal arterial blood flow velocity waveforms obtained by Doppler ultrasound examination in pregnant women. We have now completed continuous-wave Doppler ultrasonographic measurements of maternal renal arterial blood flow, and we assessed changes in renal blood flow in pregnant patients with hydronephrosis.

Patients and methods

Seventy-two continuous-wave Doppler ultrasonographic examinations were performed on nine nonpregnant and 56 normal pregnant Japanese women who were seen in our clinics at Shimane Medical University Hospital. The range of gestation was 6 to 40 weeks. Permission was obtained from each woman for the study.

We used an Aloka SSD-730 with a 2 MHz transducer, and it is applicable for either pulsed or continuous-wave Doppler mode. With this apparatus, simultaneous real-time imaging and Doppler tracings can be made.

*$p < 0.05$.

In the continuous-wave Doppler mode, velocities can be measured up to 6 m/sec but with loss of range resolution.

The patient was placed in the left decubitus position, and the kidneys were scanned in the longitudinal plane from the back by real-time ultrasound examination. The most dilated calyx was identified and measured from the leading edge to leading edge with electronic calipers, and classification into four groups was made.[8] The continuous-wave Doppler beam was directed to the area of the renal hilus, and a search was made for strong pulsatile signals, which indicated a reflection of the beam from the renal artery. The renal arterial blood flow velocity waveform is shown in Fig. 1. Acceleration time was measured as the interval from the start of the systolic forward phase to the maximal peak velocity in systole. The systolic per diastolic ratio (the ratio of peak systolic to least diastolic flow velocity) was calculated. On each record, three to four separate cardiac cycles were examined to determine the mean acceleration time or systolic per diastolic ratio. Statistical analysis was performed by the Student *t* test.

Results

Of 72 examinations, 68 recordings were made of the left renal artery (94.4%) and 28 were made of the right renal artery (38.9%), respectively (Table I). Of these 79 (59 left and 20 right kidneys) in pregnant women,

54 were grade 0 (caliceal diameter 0 to 5 mm), 19 were grade I (caliceal diameter 6 to 10 mm), one was grade II (caliceal diameter 11 to 15 mm), and five were grade III (caliceal diameter ≥16 mm), respectively. On the other hand, grade 0 was 16 and grade I one of 17 (nine left and eight right kidneys) in nonpregnant women. There was no correlation between acceleration time and systolic per diastolic ratio and gestational age, respectively. There was also no correlation between acceleration time and systolic per diastolic ratio and the caliceal diameter. Acceleration times of the left and right renal arteries were 47 ± 11 and 40 ± 8 msec in nonpregnant women, and 62 ± 23 and 62 ± 23 msec in pregnant women, respectively (Table II).

Acceleration time in pregnant women was slightly longer than that in nonpregnant women ($p < 0.05$). The left and right systolic per diastolic ratios were 3.1 ± 0.7 and 2.9 ± 0.5 in nonpregnant women and 2.8 ± 0.6 and 2.6 ± 0.5 in pregnant women, respectively (Table II).

Comment

With advances in high-resolution ultrasonic equipment, an appropriate observation of cases of maternal hydronephrosis during pregnancy can be made.[1, 2] Fried[2] found that the onset of dilatation was earlier than that reported, the degree of hydronephrosis in the right kidney predominated, and that there was a gradual increase in the extent of dilatation throughout pregnancy. Peake et al.[3] used renal caliceal diameter as an index of hydronephrosis and noted a gradual increase in dilatation throughout pregnancy; the rate of increase was greater in the right than in the left kidney. In our study, 25 of 79 kidneys each (31.6%) in pregnant women showed some dilatation of the renal pelvis, and five with grade III hydronephrosis (severe dilatation, caliceal diameter ≥16 mm)[3] were right sided.

Sampson[7] was the first to measure renal arterial blood flow velocity waveform by Doppler ultrasound examination and to monitor the rejection process in human renal allotransplants. In the case of healthy subjects, the renal arterial blood flow pattern is composed of a fast systolic forward flow followed by a gradually slowing diastolic flow continuing to end-diastole.[9] On the other hand, a significant correlation was observed between the acceleration time of flow velocity waveform and graft function, and there was no correlation among systolic per diastolic ratio and graft function.[8] In healthy subjects, the acceleration time was 50 ± 7 msec, and the systolic per diastolic ratio was 3.4.[3] In the present study, there was no correlation between acceleration time and systolic per diastolic ratio and gestational age, respectively, and no correlation was found between acceleration time and systolic per diastolic ratio and caliceal diameter of the renal pelvis. Acceleration times of the left and right renal arteries were 47 ± 11 and 40 ± 8 msec in nonpregnant women and 62 ± 23 and 62 ± 23 msec in pregnant women, respectively. The left and right systolic per diastolic ratios were 3.1 ± 0.7 and 2.9 ± 0.5 in nonpregnant women, and 2.8 ± 0.6 and 2.6 ± 0.5 in pregnant women, respectively. Therefore these data provide a foundation for the study of hydronephrosis of pregnancy.

Kinoshita[9] reported that abnormalities of renal arterial blood flow velocity waveform were seen in cases of renal parenchymal damage, such as chronic glomerulonephritis and hydronephrosis. Therefore Doppler ultrasound examination is a pertinent tool when attempting to assess renal function and circulatory dynamics in cases of preeclampsia, toxemia of pregnancy, and other renal disease occurring in pregnant women.

We thank K. Oka for assistance with the examinations and M. Ohara for advice on the manuscript.

The endocrinologic evaluation of a 45,X true hermaphrodite

Gregory F. Rosen, M.D., Michael Vermesh, M.D., Gerrit d'Ablaing III, M.D., Stephen Wachtel, Ph.D., and Rogerio A. Lobo, M.D.

Los Angeles, California, and Memphis, Tennessee

A 13-year-old 45,X girl presented with spontaneous menses and the acute onset of progressive hirsutism. Complete endocrinologic evaluation of hirsutism was unremarkable. An exploratory laparotomy revealed a gonad containing ovarian and testicular tissue. Chromosome analysis from four different tissues confirmed the karyotype to be 45,X. She was H-Y antigen positive. (AM J OBSTET GYNECOL 1987;157:1272-3.)

Key words: True hermaphrodite, Turner's syndrome, hirsutism

A true hermaphrodite is an individual whose gonad(s) contain ovarian tissue with follicles and testicular tissue with spermatozoa or seminiferous tubules.[1] (Women with a 45,X chromosomal complement have either streak gonads containing ovarian stroma devoid of follicles or, rarely, present with normal ovarian tissue.) We present the first case of a 45,X true hermaphrodite. Diagnosis was made after the patient complained of the acute onset of progressive hirsutism.

Case report

This patient first presented to our clinic with the diagnosis of Turner's syndrome and was referred because of vaginal bleeding. A chromosomal analysis had been performed on peripheral lymphocytes in the neonatal period to establish a diagnosis. Starting at age 12 years 4 months, she described the spontaneous onset of vaginal bleeding. This occurred twice more over the next 6 months. Thelarche and pubarche preceded menstruation by approximately 8 months. The rest of her history was unremarkable. At physical examination of this 13-year-old girl (height = 54 inches; weight = 70 pounds), classical Turner's facies, T3 breasts, and P3 pubic hair were present. There was no evidence of androgen excess. External genitalia and vaginal mucosa demonstrated an estrogenic effect. Blood was noted to be coming from the cervical os. The uterus was normal and ovaries were not palpable. Laboratory evaluation revealed elevated gonadotropin levels (luteinizing hormone, 56 mIU/ml; follicle-stimulating hormone, 225 mIU/ml) with a low serum estradiol level (10 pg/ml) at the time of this menses. The assessment at the time was that she was having periodic follicular development.

She returned to the clinic 5 months later complaining of the rapid onset of hirsutism and acne. The Ferriman/Gallwey system was used to score the hirsutism. She was given a score of 14 (lip 3, chest 2, lower back 3, lower abdomen 2, forearm 2, and thigh 2) with normal being <4 and only 1.2% of women scoring >10. Hirsutism is not an associated finding in Turner's syndrome. A bimanual pelvic examination and an ultrasound examination failed to demonstrate a pelvic mass. Serum androgen levels, except for dehydroepiandrosterone sulfate, were within normal limits for a peripubertal woman (testosterone = 29 ng/ml; non–sex hormone binding globulin bound testosterone = 9%; androstenedione = <20 ng/dl; initial dehydroepiandrosterone sulfate = 3.73 and repeat 2.80 μg/ml). Adrenal status was evaluated by an adrenocorticotropic hormone stimulation test (17-hydroxy progesterone: before test, 1.91 ng/ml; after test, 2.08 ng/ml) and a computed tomographic scan of the adrenals, which was normal.

Patients with idiopathic hirsutism have elevated levels of 5α-reductase activity in the skin. In order to ascertain whether this patient had increased 5α-reductase activity and therefore increased end-organ sensitivity to testosterone, pubic skin was analyzed for 5α-reductase activity in vitro. She demonstrated a normal conversion of testosterone to dihydrotestosterone (1.64%/200 mg/hr; normal 1% to 5% per 200 mg per hour).

There was no reasonable explanation for the hirsutism so a laparotomy was performed to evaluate the gonads for a Y line. Uterus and fallopian tubes were normal; there was a streak gonad on the left and a small gonad measuring 2.3 by 1.5 by 1.3 cm on the right. Blood was taken from the ovarian veins bilaterally and was analyzed for testosterone and estradiol. A gradient was demonstrated between the right gonad and the periphery (right gonad: estradiol = 108 pg/ml, testosterone = 48.4 ng/dl; peripheral vein: estradiol = 50 pg/ml, testosterone = 19.4 ng/dl).

Pathologic examination of the streak gonad showed only fibrous tissue but the right gonad revealed a dysgenetic gonad with mature graafian follicles with ova, a marked decrease in the number of primordial follicles; Sertoli-Leydig cells, and well-developed seminiferous tubules. This established the diagnosis of true

hermaphroditism. Chromosome analysis was performed on tissue from each gonad, skin, and lymphocytes. One hundred cells from each source were counted, and karyotypes of 10 from each were determined. All results confirmed the original karyotype of 45,X. The H-Y antigen status was positive and the postoperative estradiol, testosterone, and dehydroepiandrosterone sulfate levels were 16 pg/ml, <10 ng/ml, and 2.6 μg/ml, respectively.

Comment

We present here the first description of a 45,X true hermaphrodite. It is impossible to prove that mosaic lines do not exist, for example, a 46,XX line to explain menstrual function. However, this cell line could not be demonstrated even though karyotypes of the ovotestis and three other tissues were determined and a total of 400 cells were counted. The presence of the H-Y antigen is expected with the finding of testicular tissue. The mechanism of hirsutism in this patient remains unexplained because the androgen levels were never found to be sufficiently elevated and she had normal 5α-reductase activity. However, hirsutism has been reported previously in a patient with gonadal dysgenesis and low levels of androgens.[2] We concur that surgical evaluation of the gonads should be performed if no other explanation of hirsutism can be found to evaluate the possibility of a Y line in patients with a 45,X karyotype.

Hyperimmunoglobulinemia E and pregnancy: A case report

Connie Lindenbaum, M.D., Ashwin Chatwani, M.D., Rosanne Oyer, M.D., and John Fitzgerald, D.O.
Philadelphia, Pennsylvania

Hyperimmunoglobulinemia E is characterized by recurrent bacterial sinopulmonary and skin infections from birth or early childhood, with IgE levels at least 10 times greater than the upper limits of normal. The following case describes a young black woman with hyperimmunoglobulinemia E syndrome who had an uneventful pregnancy and delivery. The infant has been diagnosed as suffering from hyperimmunoglobulinemia E syndrome as well. (Am J Obstet Gynecol 1987;157:1273-4.)

Key words: Hyperimmunoglobulinemia E, pregnancy

A case is presented of a young black woman with hyperimmunoglobulinemia E syndrome.

Case report

P. D., a 21-year-old black woman, gravida 1, para 0, was seen in our prenatal clinic for the first time at 13 weeks' gestation. The patient had been followed up at the Children's Hospital of Philadelphia because of hyperimmunoglobulinemia E syndrome for more than 10 years. She has suffered from recurrent sinopulmonary infections with resultant chronic obstructive pulmonary disease, as well as recurrent staphylococcal skin infections with abscess formation requiring dicloxacillin and drainage.

The patient's family history includes a brother with hyperimmunoglobulinemia E and a sister who died from complications of hyperimmunoglobulinemia E.

Physical examination revealed a well-developed black woman with coarseness of facial features and scarring of the face and skin. She had onycholysis and mild clubbing of the distal phalanges. Examination of the lungs revealed scattered rhonchi. The pelvic examination revealed the uterus to be compatible with a 13-week pregnancy.

The laboratory studies revealed a white blood cell count of 6300/mm^3 with 50 neutrophils, 16 eosinophils, 26 lymphocytes, and eight monocytes. The serum IgE level was >10,000 IU/ml (n = 195) and the antistaphylococcal IgE was 13.5 (n = 0).

The pregnancy progressed uneventfully until the twenty-seventh week of gestation, when the patient was admitted with an exacerbation of bronchitis and de-

hydration. The dehydration was secondary to diarrhea. Stool examination revealed giardiasis. The patient was treated with nafcillin and furazolidone.

Beginning at 28 weeks, the patient underwent serial ultrasound examination for evaluation of fetal growth.

The patient was readmitted at 32 weeks' gestation with productive cough and weight loss. The sputum culture revealed *Pseudomonas* and *Proteus* bacteria. The patient was treated with cefaclor. She was also noted to have a gingival abscess that required surgical drainage.

The patient had no further antepartum complications and went into spontaneous labor on October 18, 1986, at 40 weeks' gestation. She was delivered of a healthy baby girl weighing 6 pounds 7 ounces. The postpartum period was uneventful. At a follow-up postpartum visit the patient was doing well. Her infant has recently been diagnosed as having hyperimmunoglobulinemia E syndrome and is taking oral dicloxacillin and steroid skin cream.

Comment

In 1966, Davis et al[1] described two female patients with fair skin, reddish hair, severe eczema, dystrophic fingernail changes, severe sinopulmonary infections, and recurrent staphylococcal abscesses. The abscesses did not show any surrounding erythema and were termed "cold abscesses." The newly perceived syndrome was called Job's syndrome from the biblical quotation. Subsequent work by others[2] has revealed that the syndrome is not limited to red-haired women, as it has been described in men and black persons.

Patients with hyperimmunoglobulinemia E syndrome have IgE levels at least 10 times greater than normal and a chemotactic defect in circulating neutrophils.[3] The patients usually have coarse facial features with a broad nasal bridge, a prominent nose, and irregularly prepositioned cheeks and jaws. *Candida* infections of the nails, mouth, and vagina are common. A familial occurrence has been observed without any definite inheritance pattern.

There have been no reported cases in the literature of pregnancy in these patients. The effect of hyperimmunoglobulinemia E syndrome on pregnancy is not known because this is a rare condition. Our patient was delivered of a healthy newborn infant at term.

We recommend that patients with hyperimmunoglobulinemia E syndrome undergo regular surveillance for detection of signs of infection. This will permit timely diagnosis and prevent sepsis. Pulmonary complications should be managed promptly and aggressively to prevent hypoxia. Fetal ultrasound examination should be done in the third trimester to assess fetal growth in the face of chronic obstructive pulmonary disease. The neonate should be screened for hyperimmunoglobulinemia E, as a familial inheritance can occur, as happened in this case.

2-Chloroprocaine for local perineal infiltration

Elliot H. Philipson, M.D., Betty R. Kuhnert, Ph.D., and Carol D. Syracuse, B.S.
Cleveland, Ohio

Lidocaine was recently found to rapidly cross the placenta and result in considerable fetal exposure after local infiltration of the perineum for episiotomy. For this reason, a more appropriate agent for local perineal infiltration might be a drug with rapid metabolism and inactive metabolites. 2-Chloroprocaine, an ester-linked local anesthetic agent, is available but is not commonly used for this procedure. The purpose of this study was to evaluate the placental transfer of 2-chloroprocaine after local perineal infiltration. The drug was administered to 17 normal term pregnant women for episiotomy. After local perineal infiltration, the levels of 2-chloroprocaine and/or its metabolite, chloroaminobenzoic acid, were quantitated in maternal and neonatal plasma or urine. The pharmacologic data indicated that 2-chloroprocaine was nondetectable at delivery in maternal and umbilical cord vein; one patient had trace levels in the cord. Chloroprocaine was not detectable in neonatal plasma, but chloroaminobenzoic acid was detectable in both maternal and cord vein plasma. Mean levels of chloroaminobenzoic acid in maternal plasma at delivery were 1.04 ± 0.32 μg/ml, and mean levels in cord vein were 0.35 ± 0.54 μg/ml. Clinically, 2-chloroprocaine provided good analgesia. These results indicate that very little, if any pharmacologically active drug, reaches the fetus after local perineal infiltration with 2-chloroprocaine. Therefore 2-chloroprocaine appears to be preferable to lidocaine when used for local perineal infiltration. (Am J Obstet Gynecol 1987;157:1275-8.)

Key words: 2-Chloroprocaine, perineal infiltration, chloroaminobenzoic acid

Local infiltration of the perineum is a commonly performed procedure used to provide analgesia for episiotomy. The most commonly used local anesthetic agent for this purpose has been lidocaine. Since small quantities of lidocaine were used and administration occurred very close to delivery, it was assumed that very little drug would reach the fetus. However, in a recent study, lidocaine was found to rapidly cross the placenta with considerable drug levels in the umbilical cord vein at delivery.[1] Furthermore, the rapid placental transfer of lidocaine resulted in a mean fetal-maternal ratio significantly higher than that found with much larger doses of lidocaine for lumbar epidural anesthesia.

Thus lidocaine crosses the placenta in considerable amounts after local perineal infiltration. Furthermore, lidocaine is metabolized slowly in the liver into two pharmacologically active metabolites. Therefore other local anesthetic agents may be more appropriate for local perineal infiltration. One possibility is 2-chloroprocaine, an ester-linked local anesthetic agent that is rapidly metabolized by plasma enzymes into inactive metabolites.

From the Perinatal Clinical Research Center, Cleveland Metropolitan General Hospital, and Case Western Reserve University.
Supported in part by U.S. Public Health Service Perinatal Clinical Research Center Grant No. M01-RR00210.
Received for publication January 8, 1987; revised May 4, 1987; accepted June 3, 1987.
Reprint requests: Elliot H. Philipson, M.D., Department of Obstetrics and Gynecology, Cleveland Metropolitan General Hospital, 3395 Scranton Road, Cleveland, Ohio 44109.

The purpose of this study was to determine (1) the disposition of 2-chloroprocaine and its metabolite, 2-chloroaminobenzoic acid, in mother, fetus, and neonate after local perineal infiltration and (2) if 2-chloroprocaine provides adequate pain relief.

Material and methods

Patients. Seventeen normal gravida at term from the obstetric service at Cleveland Metropolitan General/Highland View Hospital were studied. Informed consent for sample collection was obtained in early labor. Local infiltration of the perineum with 1% 2-chloroprocaine was administered as needed for episiotomy. No patients had a history of liver or kidney disease or of known drug abuse.

Procedure. Local perineal infiltration was performed with a 22-gauge needle. 2-Chloroprocaine without epinephrine was injected superficially into the area of the posterior fourchette during the crowning phase of the second stage of labor. The drug was injected as needed, and the amount injected was determined by the physician. The total dose of 2-chloroprocaine (milligrams) and the time (minutes) from administration to delivery (the drug-to-delivery interval) were recorded.

Sample collection. Maternal blood samples (3 ml) were collected from an indwelling cannula in a peripheral arm vein. After a premedication blood sample was obtained, blood samples were collected after local perineal infiltration at 1, 3, 5, 7, 10, 20, and 30 minutes or until delivery, at which time the final sample was drawn. Postpartum maternal blood samples were

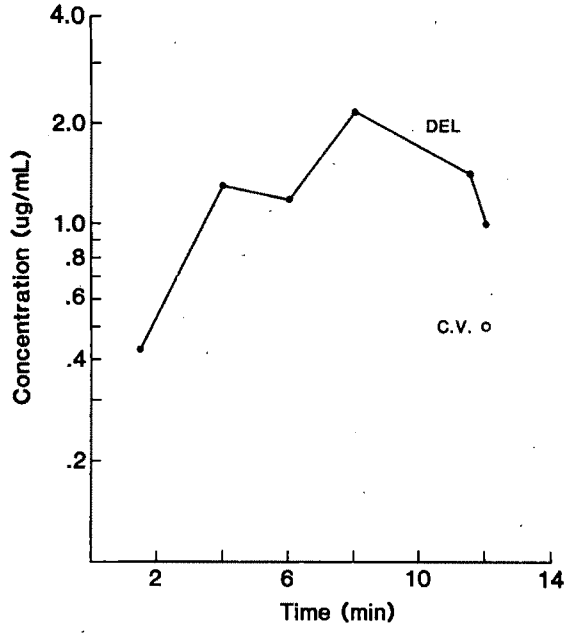

Fig. 1. Maternal plasma concentration of chloroaminobenzoic acid after local perineal infiltration with 8 ml of 1% 2-chloroprocaine (80 mg). (*C.V.* = Cord vein; *DEL* = delivery.)

obtained at 24, 48, and 72 hours after delivery. All samples were immediately put into heparinized Vacutainers and placed on ice. Samples to be analyzed for 2-chloroprocaine and chloroaminobenzoic acid levels were collected in Vacutainers containing 0.3 ml of a cholinesterase inhibitor, echothiophate iodide, 0.2 gm/ml (Ayerst Laboratories, New York, New York); samples analyzed for cholinesterase activity were obtained in Vacutainers without the inhibitor. The plasma was removed after centrifugation and frozen until assayed.

Neonatal blood samples were obtained at birth from a doubly clamped section of umbilical cord and at 24, 48, and 72 hours of age by either heel stick or venipuncture. Neonatal urine samples were collected in plastic urine collection bags (Hollister Newborn U-Bag, Libertyville, Illinois). Collection of six consecutive 6-hour samples was attempted, but collections were stopped if signs of skin irritation occurred. All urine samples were frozen until analyzed.

Specimen analysis. Plasma levels of 2-chloroprocaine were analyzed by single ion-monitoring gas chromatography and mass spectrometry.[2] The sensitivity of this method is 1 ng/ml of plasma. Plasma and urine levels of chloroaminobenzoic acid were analyzed by gas chromatography with a modification of a previously reported method.[3] The modifications included use of an electron capture detector for increased specificity and use of diiodoaminobenzoic acid as an internal standard. The sensitivity of this method is 50 ng/ml. Total chloroaminobenzoic acid in neonatal urine was analyzed. No attempt was made to distinguish between free and bound chloroaminobenzoic acid since only trace levels of conjugated chloroaminobenzoic acid have been reported in neonates.[4] Urinary chloroprocaine levels were not determined. Plasma cholinesterase activity and the dibucaine number were determined by spectrophotometry for documentation of normal cholinesterase levels.[5]

Pharmacokinetic analysis. Fetal-maternal ratios were calculated by dividing the amount of chloroaminobenzoic acid in the cord vein at birth by the amount in the maternal vein at birth. Disappearance of chloroaminobenzoic acid from urine was monitored by recording drug concentration in micrograms of drug excreted per milliliter against hours after delivery for the neonate.

Clinical evaluation. The quality and duration of pain relief were evaluated subjectively by each patient. If additional pain relief was required because of an extension of the episiotomy or a laceration of the vaginal mucosa, 1% lidocaine was administered.

Newborn evaluation consisted of 1- and 5-minute Apgar scores and fetal acid-base status from the umbilical cord vein. Each infant was weighed postpartum and underwent a complete physical examination, and gestational age was determined by the Ballard modification of the Dubowitz examination.[6]

Results

Patient population. The maternal, neonatal, and intrapartum anesthesia characteristics of the 17 study patients are shown in Table I. The mothers were at term and without any underlying obstetric problems. All neonates had Apgar scores of >7 at 5 minutes. Four

neonates had 1-minute Apgar scores <7. Three of these neonates had thick meconium at delivery and required endotracheal suctioning immediately. The other neonate had a shoulder dystocia. The mean pH of the umbilical cord blood at delivery was 7.32 ± 0.05. There were no signs of anesthetic toxicity in any of the neonates.

Plasma drug levels. 2-Chloroprocaine was not detectable in maternal plasma after local perineal infiltration or at delivery. Detectable levels of 2-chloroprocaine were found at delivery in only one umbilical cord vein sample. The concentration in this one umbilical cord was 4.84 ng/ml. 2-Chloroprocaine was not detectable postpartum in neonatal plasma.

The appearance of chloroaminobenzoic acid was rapid and detectable in all patients before delivery. An example of a maternal plasma concentration time profile is shown in Fig. 1. As seen in this figure, the highest maternal plasma level of chloroaminobenzoic acid (2.13 μg/ml) occurred 8 minutes after receiving 8 ml of 1% 2-chloroprocaine (80 mg).

The mean, standard deviation, and range of chloroaminobenzoic acid concentration at delivery in the maternal plasma and umbilical cord vein are shown in Table II. The means were 0.62 and 0.28 μg/ml, respectively. The fetal-maternal ratio of chloroaminobenzoic acid at delivery ranged from 0.32 to 1.39, with a mean of 0.80.

Urine drug levels. Thirty-one samples were collected from nine neonates. Seven of the nine neonates had measurable levels of chloroaminobenzoic acid in their urine. Half of the samples had levels of chloroaminobenzoic acid below the detection limit (50 ng). The concentrations ranged from 0 to 2.4 μg/ml. Urinary chloroaminobenzoic acid was detectable in some neonates 36 hours post partum.

Clinical evaluation. The quality and duration of pain relief as judged by each patient were adequate. There were no adverse effects. The quality and duration of analgesia as evaluated by the obstetrician were sufficient except in two patients in whom additional local anesthetic was necessary for fourth-degree episiorrhaphies.

Comment

The purpose of this study was to describe the disposition of 2-chloroprocaine and its metabolite, chloroaminobenzoic acid, in mother and neonate after local perineal infiltration. The key finding of this study indicates that very little, if any, unchanged 2-chloroprocaine reaches the fetus after local infiltration of the perineum with 2-chloroprocaine.

These results are similar to those from previous studies of 2-chloroprocaine administered by other routes. 2-Chloroprocaine has been shown to reach the fetus in only small amounts after paracervical block and lumbar epidural anesthesia.[3, 7] This apparent lack of placental transfer occurs because 2-chloroprocaine is rapidly metabolized by maternal plasma cholinesterases. This rapid metabolism was evidenced immediately by detectable chloroaminobenzoic acid levels and nondetectable levels of 2-chloroprocaine. In the present study, trace levels of 2-chloroprocaine were found in only one umbilical cord vein sample at delivery. Any unchanged 2-chloroprocaine that crossed the placenta was probably metabolized by fetal plasma cholinesterases.[8, 9] Although fetal levels in utero were not measured, these data suggest that very little active drug reaches the fetus after local perineal infiltration with 2-chloroprocaine.

Table II. Chloroaminobenzoic acid concentration (micrograms per milliliter) at delivery in maternal plasma and umbilical cord vein after local perineal infiltration

Sample	*Concentrations*	
Maternal plasma (at delivery)*	0.62 ± 0.38	(0.36-1.31)
Umbilical cord vein	0.28 ± 0.42	(0-1.43)
Fetal/maternal ratio†	0.80 ± 0.47	(0.32-1.39)

*Mean ± standard deviation with range in parentheses.
†Ratio of level in cord vein to level in maternal vein at delivery (mean of individual ratios and not ratio of means).

The neonatal excretion of chloroaminobenzoic acid has been reported after administration of 2-chloroprocaine for paracervical block and lumbar epidural anesthesia.[3, 4, 7] These reports consistently indicate that the neonate excretes less than 0.25% of the total maternal dose as chloroaminobenzoic acid. These findings support the premise that very little active drug reaches the fetus after local perineal infiltration with 2-chloroprocaine.

The fetal-maternal ratio of chloroaminobenzoic acid (0.80) is similar to the fetal-maternal ratio reported for lumbar epidural anesthesia for cesarean section and for paracervical block.[3, 4, 7] The clinical data revealed no adverse effects of 2-chloroprocaine or chloroaminobenzoic acid on the mother, fetus, or neonate. More important, 2-chloroprocaine provided adequate analgesia for the episiorrhaphy except in two patients who required additional local anesthetic for a fourth-degree episiorrhaphy.

What clinical significance, if any, do the results of this study have? A previous study indicated that a common, obstetric procedure traditionally performed with lidocaine can result in considerable neonatal drug exposure.[1] In fact, neonatal lidocaine toxicity with convulsions has been reported after accidental scalp injection with lidocaine at the time of episiotomy.[10] This study suggests that this exposure can be minimized

with the use of an equally effective, alternative, pharmacologic agent that is metabolized differently. Hence 2-chloroprocaine, an ester-linked local anesthetic agent, may be preferable to lidocaine for local perineal infiltration.

Breast galactography in the treatment of infected cysts

Dennis P. Tihansky, M.D., Ph.D., and Joseph A. DiBlasio, M.D.
Valhalla, New York, and Clarksburg, West Virginia

Galactography is a valuable procedure to localize the cause of nipple duct secretions or hemorrhage. A unique variant is illustrated by cannulating a periareolar sinus tract, which drains from an infected epidermoid cyst communicating with several ducts. (Am J Obstet Gynecol 1987;157:1278-80.)

Key words: Galactography, mammography, breast, cyst, fistula

Among examinations for the evaluation of abnormal breast discharge, routine mammography is generally ordered for initial screening. However, its false-negative rate is high, such that only half of malignant tumors are typically identified on routine films.[1] Galactography yields a more detailed image of ductal disease on injection of contrast medium into the affected nipple duct. We report for the first time a galactogram variant in which a draining fistula is cannulated outside the areolar zone to demonstrate an inflamed epidermal cyst.

Method

After a scout mammogram is taken, the breast drainage site is cleaned, and the draining duct or sinus tract is gently cannulated with a 27-gauge blunt needle. Radiopaque contrast medium is slowly injected until the patient complains of discomfort or until it leaks around the needle. If the gynecologist anticipates interventional therapy, methylene blue dye can also be injected to delineate the extent of the inflammatory or neoplastic process. Mammography films are then taken at the end of the procedure.

Case report

A 24-year-old white woman with fibrocystic disease had pain and swelling in her upper right breast, in addition to purulent drainage from a nipple duct. Six months earlier, she had an infected cyst lanced and drained within this area, but soon afterward the nipple discharge recurred and a sinus tract formed and drained along the supraareolar ridge.

Mammograms revealed extensive dysplasia but no dominant mass or skin thickening. A galactogram was performed next, but no fluid could be expressed from the nipple, so the draining sinus tract rather than the occluded duct was cannulated (Fig. 1). The contrast

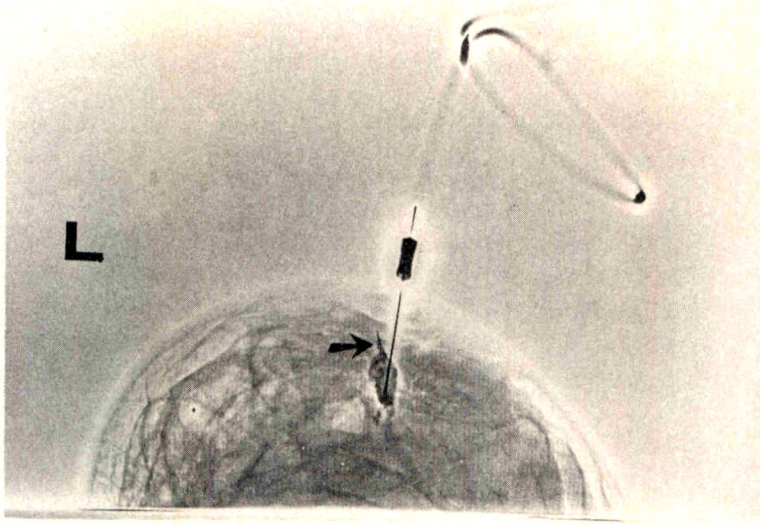

Fig. 1. Injection of contrast medium via the sinus tract into the cavity and partially occluded nipple duct *(arrow)*.

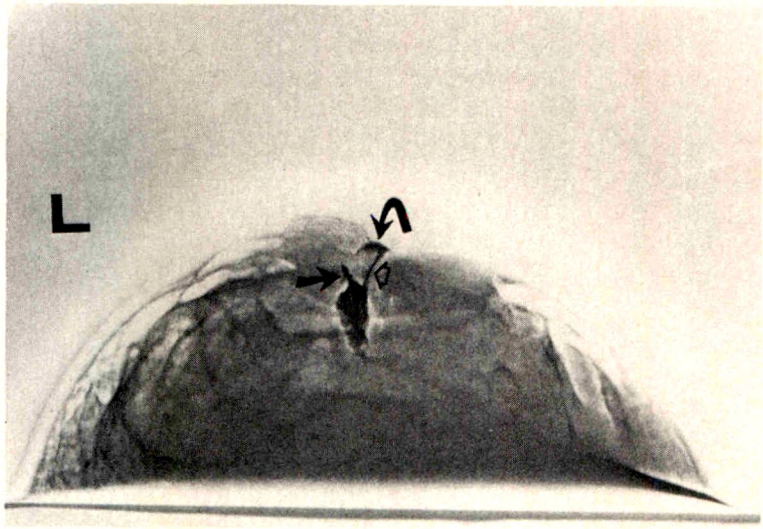

Fig. 2. Contrast opacification of the cavity with the sinus tract *(open arrow)*, partially occluded nipple duct *(straight arrow)*, and leakage outside the injection site *(curved arrow)*.

medium filled a small, irregular cavity connected with two occluded ducts, one of which extended deep into the breast and the other toward the nipple. On removal of the cannula, a final mammogram (Fig. 2) outlined the short sinus tract and internal communicating structures.

Examination of the biopsy specimen of the cavitary wall showed that it was an infected epidermoid cyst, which was derived from the epithelium around a hair follicle. After methylene blue dye was injected into the cyst, tissue resection was confined to the inflamed area. Major lumpectomy was thus avoided with good cosmetic results.

Comment

From its earliest use more than half a century ago,[2] galactography remains a key procedure for the evaluation of breast ductal diseases. Galactograms may delineate abnormalities such as filling defects, ductal caliber changes, amputation, or partial occlusion, and splaying or displacement of ducts. When properly performed, this procedure is more accurate and specific than the alternatives, including mammography, thermography, ultrasonography, transillumination, or clinical palpation.

There is no contraindication to its use, although be-

fore the introduction of water-soluble contrast medium, sequelae of pain or inflammation were cited after oily injections.[2] Among causes of serous or bloody discharge, papillomas are most frequently reported with an incidence of 40% compared to carcinoma with a lower incidence of 10%.[1] Thus galactography is an optimal technique for the diagnosis and delineation of duct- or even fistula-related diseases of the breast.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Effects of the antiprogesterone RU 486 on preterm birth in the rat

R. E. Garfield, Ph.D., J. M. Gasc, Ph.D., and E. E. Baulieu, M.D.
Hamilton, Ontario, Canada, and Paris, France

The effects of the antiprogesterone compound RU 486 on preterm delivery, myometrial gap junctions, and plasma levels of steroid hormones were investigated in pregnant rats. Injection of RU 486 on day 16 of gestation resulted in prolonged delivery beginning after 24 hours. The preterm birth initiated by RU 486 was preceded and accompanied by the extensive development of gap junctions between myometrial cells. R 5020, but neither progesterone nor dexamethasone, prevented preterm birth and the development of gap junctions. Estrogen and progesterone levels declined after RU 486 treatment but only after a major proportion of the fetuses were delivered. This study indicates that progesterone may normally inhibit uterine contractility by suppressing the genome responsible for the expression of gap junctions. (Am J Obstet Gynecol 1987;157:1281-5.)

Key words: Progesterone, labor, gap junctions, pregnancy, myometrium

The antiprogesterone compound RU 486 binds with high affinity to the progesterone receptor to inhibit the action of the hormone.[1] In some species, such as rats, rabbits, and sheep, elevated uterine levels of progesterone are thought to be required for the maintenance of pregnancy, and the decline in the hormone is believed to initiate labor.[2] The events that initiate human labor have never been adequately documented, and the role of progesterone has been the subject of much controversy. However, in all species studied including humans, treatment with RU 486 either prevents implantation, if given early or initiates parturition when given late in gestation,[1] indicating the importance of progesterone in maintaining pregnancy in all animals. The mechanism by which progesterone and the antihormone act to respectively sustain pregnancy and prevent or interrupt it is not understood. It is known that the withdrawal of progesterone stimulates the development of gap junctions between myometrial cells by estrogen-dependent mechanisms in rodents.[3, 4] Furthermore, these cell-to-cell contacts seem essential for the coordination of myometrial contractility in all species since they are present only in large numbers during term and preterm labor in humans and other species studied.[3-4] The presence of gap junctions appears to explain how hormonal regulation is translated into structural changes in the myometrium, which lead to conditions favoring contractility.[4] However, exactly how hormones control the development and regression of myometrial gap junctions is not completely understood. It has been suggested that either changes in steroid hormone and prostaglandin levels and/or changes in their receptors may govern the synthesis of gap junction proteins.[1-6]

In this study we treated rats at day 16 of gestation with a single injection of RU 486 and thereafter measured delivery of the fetuses, plasma levels of progesterone and estradiol, and gap junctions. Our study shows that RU 486 induced preterm delivery starting 24 hours after treatment. Fetal delivery was preceded and accompanied by the appearance of large numbers of gap junctions between the uterine muscle cells. We observed no changes in peripheral blood levels of the hormones until after 80% of the fetuses were born. These results suggest that progesterone may control the maintenance of pregnancy by reacting with its specific receptor directly in the myometrial cells to control the expression of gap junctions.

Material and methods

Pregnant rats (Sprague-Dawley strain) were injected subcutaneously with either sesame oil (controls) or sesame oil with RU 486 (10 mg/kg; Roussel Uclaf) on the morning of the sixteenth day of gestation (day 1 = sperm positive). Some RU 486-treated rats were also injected twice daily with either dexamethasone (100 μg/rat), progesterone (10 mg/rat), or R 5020

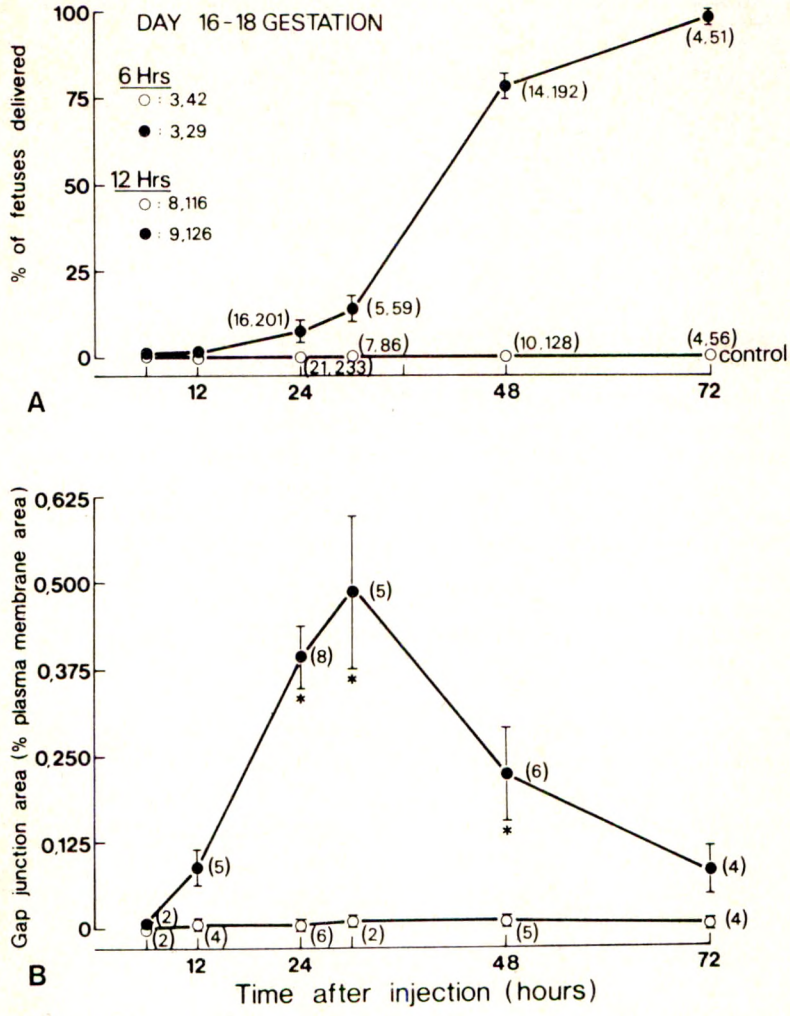

Fig. 1. Changes in delivery of fetuses **(A)** in control *(open circles)* and RU 486-treated *(closed circles)* pregnant rats. (Points represent means of percentage of total fetuses delivered ± SEM.) Numbers in brackets indicate the total number of pregnant rats and fetuses **(A)** and the number of tissues examined under the electron microscope **(B)** in each group at various times after treatment. *(Asterisk* = Mean values with significant differences [$p < 0.05$].)

(5 mg/rat). At various times some animals were killed (total pregnant rats = 144), and the number of fetuses in utero and placental attachment sites (total fetuses = 1747) were counted. Blood was collected in heparinized syringes for analysis of the steroid hormones. The midsection of one uterine horn was fixed for electron microscopy examination. Estradiol and progesterone were later assayed by radioimmunoassay. Tissues for electron microscopy were prepared as described previously.[5] The area of gap junction was determined from measurements of the lengths of junctional and nonjunctional membranes in 22 electron micrographs taken of the longitudinal muscle layers of each tissue (1 tissue/rat). Levels of significance were determined by an analysis of variance for multiple comparisons and the Student *t* test for pairwise comparisons ($p < 0.05$ = level of significant differences).

Results

Fig. 1, *A* shows the mean percentage of fetuses delivered (number of deliveries/total fetuses/rat for all rats in each group ± SEM) in control and RU 486-treated rats from 6 to 72 hours after injection. There were no obvious deliveries in control rats at any time despite the observation that some fetuses failed to develop (about 2%). There were also no deliveries in the RU 486-treated animals after 6 and 12 hours of treatment. At 24 hours after RU 486 injection, most rats had vaginal bleeding, and about 10% of the fetuses had been born. Between 30 and 48 hours, the greatest number of fetuses were delivered (about 70%). Thereafter to 72 hours, all remaining fetuses were expelled (about 20%). Treatment of other RU 486-injected rats with either dexamethasone (n = 13) or progesterone (n = 10) failed to significantly alter the delivery pattern

Fig. 2. Electron micrograph of myometrial tissue from a rat that delivered after 30 hours treatment with RU 486. (Original magnification ×146,000.)

as seen with RU 486 alone. However, treatment of animals with RU 486 and R 5020 (n = 16) completely prevented the preterm delivery produced with RU 486 alone (data not shown). No maternal deaths occurred after any of the treatments. Fetal deaths in utero were not apparent before 48 hours after RU 486 treatment but were present in about half the fetuses remaining (i.e., about 10% total) after 48 hours. None of the fetuses survived after birth, which was probably attributable to their prematurity.

The mean area of gap junction membrane (percentage of plasma membrane area ± SEM) between muscles cells in myometrial tissues from control and RU 486-treated rats is shown in Fig. 1, *B*. Only a few small gap junctions were found in tissues from control animals at all times. In contrast, tissues from animals that received RU 486 contained significantly higher ($p < 0.05$) gap junction areas at 24, 30, and 48 hours after treatment when the greatest percentage of fetuses were delivered (Fig. 1, *B* compared with Fig. 1, *A*). Gap junction areas were low (not significantly different from control tissue) at 72 hours after delivery of all fetuses. Similarly, gap junction areas were high in the delivery of rats treated with either RU 486 and dexamethasone (percentage area = 0.305 ± 0.070 at 24 hours, n = 4, and 0.180 ± 0.092 at 48 hours, n = 4) or RU 486 and progesterone (percentage area = 0.278 ± 0.045 at 24 hours, n = 4 and 0.012 ± 0.008 at 48 hours, n = 4) but were not different than control values in animals that received RU 486 and R 5020 (percentage area = 0.008 ± 0.008 at 24 hours, n = 4, and 0.005 ± 0.005 at 48 hours, n = 4) that did not undergo preterm delivery.

An electron micrograph of a gap junction between muscle cells of the myometrium 30 hours after RU 486 treatment is shown in Fig. 2. The average length of the junctions was larger ($p < 0.05$; 208 ± 8 nm) in animals undergoing preterm delivery induced with RU 486 compared with control tissues (101 ± 15 nm), but the increase in area (Fig. 1, *B*) was mainly caused by the increase in the number of junctions (control = seven junctions in photographs of 21 tissues; RU 486 = 210 junctions in photos of 30 tissues).

There were no significant differences ($p < 0.05$) in plasma levels of progesterone and estradiol between control and RU 486-treated rats until 48 hours (Table I) when 80% of the fetuses were already expelled (Fig. 1, *A*) and when high values of gap junctions were present (Fig. 1, *B*). At 48 hours, progesterone was significantly lower ($p < 0.05$) in maternal plasma of all groups treated with RU 486 except those also injected with R 5020 compared with control rats. Estradiol was also significantly lower at this time in all groups treated with RU 486, including those receiving R 5020. There were no significant differences in either progesterone or estradiol between control groups and those receiving dexamethasone alone at 24 and 48 hours.

Comment

This study shows that the antiprogestin RU 486 is efficient in producing an interruption of pregnancy as noted previously for rats[7] and primates,[8] including humans.[1, 9, 10] The results suggest that the progesterone receptor is involved in the action of progesterone to inhibit labor and support pregnancy. Furthermore, these results support the hypothesis that one of the
